The findings of de la Torre et al.⁶³ have shown that MDMA displays nonlinear kinetics in humans such that administration of increasing doses, or multiple doses, leads to unexpectedly high plasma levels of the drug. Enhanced plasma and tissue levels of MDMA are most likely related to auto-inhibition of MDMA metabolism, mediated via formation of a metabolite-enzyme complex that irreversibly inactivates CYP2D6.⁶⁴ Because of the nonlinear kinetics, repeated MDMA dosing could produce serious adverse consequences due to unusually high blood and tissue levels of the drug. The existing database of MDMA pharmacokinetic studies represents a curious situation where clinical findings are well documented, whereas preclinical data even in rodents are lacking. Specifically, few studies in animals have assessed the relationship between pharmacodynamic and pharmacokinetic effects of MDMA after single or repeated doses (although see Reference 65). No studies have systematically characterized the nonlinear kinetics of MDMA in rodent or nonhuman primate models.

6.7.3 Long-Term Effects of MDMA

6.7.3.1 Long-Term Effects of MDMA on 5-HT Neurons

The adverse effects of MDMA on 5-HT systems have been widely publicized, as many studies in animals show that high-dose MDMA administration produces persistent reductions in markers of 5-HT nerve terminal integrity.⁶⁶ Table 6.7.2 summarizes the findings of investigators who first demonstrated that MDMA causes long-term (>2 weeks) inhibition of tryptophan hydroxylase activity, depletion of brain tissue 5-HT, and reduction in SERT binding and function.^{67–70} Immunohistochemical analysis of 5-HT in the CNS reveals an apparent loss of 5-HT axons and terminals in MDMA-treated rats, especially the fine-diameter projections arising from the dorsal raphe nucleus.^{71,72} Moreover, the 5-HT axons and terminals remaining after MDMA treatment appear swollen and fragmented, suggesting structural damage. Time-course studies indicate that MDMA-induced 5-HT depletion occurs in a biphasic manner, with a rapidly occurring acute phase followed

Table 6.7.2 Long-Term Effects of MDMA on 5-HT Neuronal Markers in Rats

5-HT Deficit	Dose	Survival Interval	Ref.
Depletions of 5-HT in forebrain regions as measured by HPLC-ECD	10–40 mg/kg, s.c., twice daily, 4 days	2 weeks	Commins et al. ⁶⁸
Reductions in tryptophan hydroxylase activity in forebrain regions	10 mg/kg, s.c., single dose	2 weeks	Stone et al. ⁷⁰
Loss of [³ H]-paroxetine-labeled SERT binding sites in forebrain regions	20 mg/kg, s.c., twice daily, 4 days	2 weeks	Battaglia et al. ⁶⁷
Deceased immunoreactive 5-HT in fine axons and nerve terminals	20 mg/kg, s.c., twice daily, 4 days	2 weeks	O'Hearn et al. ⁷²

by a delayed long-term phase.^{69,70} In the acute phase, which lasts for the first few hours after drug administration, massive depletion of brain tissue 5-HT is accompanied by inactivation of tryptophan hydroxylase. By 24 h later, tissue 5-HT recovers to normal levels but tryptophan hydroxylase activity remains diminished. In the long-term phase, which begins within 1 week and lasts for months, depletion of 5-HT is accompanied by sustained inactivation of tryptophan hydroxylase and loss of SERT binding and function.^{73,74}

The findings in Table 6.7.2 have been replicated by many investigators, and the spectrum of decrements produced by MDMA administration is typically described as 5-HT “neurotoxicity.” Possible mechanisms underlying MDMA-induced 5-HT deficits are not completely understood, but evidence suggests the involvement of free radicals, oxidative damage, and metabolic stress.^{75–77} As noted above, there are increasing data to support a role for toxic MDMA metabolites in mediating the long-term serotonergic effects of the drug.^{60,62} Most studies examining MDMA neurotoxicity in rats have employed intraperitoneal (i.p.) or subcutaneous (s.c.) injections of 10 mg/kg or higher, either as single or repeated treatments. Such MDMA dosing regimens are known to produce significant hyperthermia, which exacerbates 5-HT deficits.^{78,79}

There are some caveats to the hypothesis that MDMA produces 5-HT neurotoxicity. O’Hearn et al.^{71,72} showed that MDMA has no effect on 5-HT cell bodies in the dorsal raphe despite profound loss of 5-HT in forebrain projection areas. Accordingly, the effects of MDMA on 5-HT neurons are often referred to as “axotomy,” to account for the fact that perikarya are not damaged. MDMA-induced reductions in 5-HT levels and SERT binding eventually recover,^{73,74} suggesting that 5-HT terminals are not destroyed. Many drugs used clinically produce effects similar to MDMA. For instance, reserpine causes sustained depletions of brain tissue 5-HT; yet reserpine is not considered a neurotoxin.⁸⁰ Chronic administration of 5-HT selective reuptake inhibitors (SSRIs), like paroxetine and sertraline, leads to a marked loss of SERT binding and function analogous to MDMA, but these agents are important therapeutic drugs rather than neurotoxins.^{81,82} In fact, Frazer and Benmansour⁸³ have suggested that sustained downregulation of SERT binding and function underlies the efficacy of SSRIs in the treatment of depression and other mood disorders. Finally, high-dose administration of SSRIs produces swollen, fragmented, and abnormal 5-HT terminals, which are indistinguishable from the effects of high-dose MDMA and other substituted amphetamines.⁸⁴

The above-mentioned caveats raise a number of questions with regard to MDMA neurotoxicity. Of course, the most important question is whether MDMA abuse causes neurotoxic damage to 5-HT systems in humans. This complex issue is a matter of ongoing debate, which has been addressed by recent papers.^{85–87} Clinical studies designed to critically evaluate the long-term effects of MDMA are hampered by a range of factors including comorbid psychopathology and polydrug abuse among MDMA users. Animal models afford the unique opportunity to evaluate the potential neurotoxic effects of MDMA administration without many of these complicating factors.

6.7.3.2 Long-Term Effects of MDMA on Markers of Neurotoxicity

It is well accepted that MDMA produces 5-HT depletions in rat CNS, but much less attention has been devoted to the effects of MDMA on established markers of neurotoxicity such as cell death, silver-positive staining, and reactive gliosis. Support for the hypothesis of MDMA-induced axotomy relies heavily on immunohistochemical analysis of 5-HT levels, which could produce misleading results if not validated by other methods. For example, MDMA-induced loss of 5-HT could be due to persistent adaptive changes in gene expression or protein function, reflecting a state of metabolic quiescence rather than neurotoxic damage. Table 6.7.3 summarizes the effects of MDMA on hallmark measures of neurotoxicity.

Anatomical evidence reveals that MDMA does not damage 5-HT cell bodies, and functional studies support this notion. 5-HT neurons in the dorsal raphe exhibit pacemaker-like firing, which can be recorded using electrophysiological techniques.^{41,42} High-dose MDMA administration (20 mg/kg, s.c., twice daily, 4 days) has no lasting effects on 5-HT cell firing or action potential

Table 6.7.3 Effects of MDMA on Established Markers of Neurotoxicity in Rats

CNS Marker	Dosing Regimen	Survival Interval	Ref.
No change in 5-HT cell firing in raphe nuclei	20 mg/kg, s.c., twice daily, 4 days	2 weeks	Gartside et al. ⁸⁸
Increased silver-positive staining in degenerating neurons	80 mg/kg, s.c., twice daily, 4 days 25–150 mg/kg, s.c., twice daily, 2 days	15–48 h 2 days	Commins et al. ⁶⁸ Jensen et al. ⁹²
No reactive astrogliosis, as measured by a lack of change in levels of GFAP	10–30 mg/kg, s.c., twice daily, 7 days 20 mg/kg, s.c., twice daily, 4 days 7.5 mg/kg, i.p., 3 doses	2 days 3 days, 1 week 2 days, 2 weeks	*O'Callaghan et al. ⁹⁶ *Pubill et al. ⁹⁸ *Wang et al. ^{97,99}

* These investigators found no effect of MDMA on GFAP expression, at doses that significantly depleted 5-HT levels in brain tissue.

characteristics, when recordings are carried out 2 weeks after drug pretreatment.⁸⁸ The electrophysiological data in MDMA-pretreated rats differ from the effects produced by the neurotoxin 5,7-dihydroxytryptamine (5,7-DHT). In 5,7-DHT-pretreated rats, 5-HT cell firing is dramatically decreased in the dorsal raphe, in conjunction with loss of 5-HT immunofluorescence.^{89,90} Thus, 5,7-DHT produces reductions in 5-HT cell firing that are attributable to cell death, but MDMA does not.

Silver staining techniques are commonly used to identify neuronal degeneration,⁹¹ and two studies have examined the ability of MDMA to affect silver-positive staining (i.e., argyrophilia) in rat CNS. Commins et al.⁶⁸ administered single or multiple s.c. doses of 80 mg/kg MDMA to male rats, whereas Jensen et al.⁹² gave twice daily s.c. injections of 50 to 250 mg/kg. In both cases, MDMA-pretreated rats displayed dose-dependent increases in the number of silver-positive nerve terminals, axons, and cell bodies in various brain areas, with the most severe degeneration observed in frontoparietal cortex. These results provide direct strong support for MDMA-induced neurotoxicity, but certain factors must be considered when interpreting the data. First, massive daily doses of MDMA ranging from 80 to 500 mg/kg were utilized, and these doses far exceed those producing 5-HT depletions in rats (see Table 6.7.2). Second, both investigations noted the presence of argyrophilic cell bodies in the cortex of MDMA-treated rats. Because 5-HT cell bodies are not present in the cortex,⁹³ these damaged cells must be nonserotonergic. Finally, the pattern of MDMA-induced silver staining does not correspond to the pattern of 5-HT innervation or the pattern of 5-HT depletions. It seems that sufficiently high doses of MDMA can increase silver-positive staining but this does not reflect 5-HT neurotoxicity per se.

A universal response to cell damage in the CNS is hypertrophy of astrocytes.⁹⁴ This “reactive gliosis” is accompanied by enhanced expression of glial-specific structural proteins, like glial fibrillary acidic protein (GFAP). O'Callaghan et al.⁹⁵ verified that a wide range of neurotoxic chemicals increase the levels of GFAP in rat CNS, indicating this protein can be used as a sensitive marker of neuronal damage. These investigators administered twice daily s.c. injections of 10 to 30 mg/kg MDMA to rats for 7 consecutive days; under these conditions, MDMA produced large 5-HT depletions in forebrain without any changes in GFAP expression.⁹⁶ Effects of MDMA on GFAP expression have been compared to the effects of 5,7-DHT.^{96,97} At doses of MDMA and 5,7-DHT that cause comparable 5-HT depletions, only 5,7-DHT increases GFAP. Several recent reports from our laboratory and others confirm that MDMA-induced 5-HT depletions are not associated with increased GFAP expression.^{97–99} Taken together, the majority of data from rats indicate that doses of MDMA causing significant 5-HT depletions (i.e., single or repeated doses of 10 to 20 mg/kg) do not induce cell death, silver-positive staining, or glial activation, suggesting these doses may not cause neuronal damage.

6.7.4 Interspecies Scaling and MDMA Dosing

6.7.4.1 Allometric Scaling and MDMA Dosing Regimens

A major point of controversy relates to the relevance of MDMA doses administered to rats when compared to those self-administered by humans (see References 40 and 48). As noted above, MDMA regimens that produce 5-HT depletions in rats involve administration of one or more doses of 10 to 20 mg/kg, whereas the amount of “Ecstasy” abused by humans is one or two tablets of 80 to 100 mg, about 1 to 3 mg/kg. Based on principles of “interspecies scaling,” some investigators have proposed that high noxious doses of MDMA in rats correspond to recreational doses in humans.¹⁰⁰ The concept of interspecies scaling is based on shared biochemical mechanisms among eukaryotic cells (e.g., aerobic respiration), and was initially developed to describe variations in basal metabolic rate (BMR) in animal species of different sizes.^{101,102} In the 1930s, Kleiber derived what is now called the “allometric equation” to describe the relationship between BMR and body weight. The generic form of the allometric equation is $Y = aW^b$, where Y is the variable of interest, W is the body weight, a is the allometric coefficient, and b is the allometric exponent. In the case where Y is BMR, b is accepted to be 0.75. In agreement with predictions of the allometric equation, smaller animals are known to have faster metabolism, heart rates, and circulation times, leading to faster clearance of exogenously administered drugs.

Unfortunately, the allometric equation is not always a valid predictor of drug dosing across species, especially for those compounds that are extensively metabolized in the liver.^{103,104} As outlined previously, MDMA is readily metabolized *in vivo* (see Figure 6.7.6).^{56,59} There are significant species differences in the expression level and functional activity of cytochrome P450 isoforms involved in the metabolism of MDMA.^{59,60} The potential for nonlinear kinetics complicates comparative aspects of MDMA metabolism, and no information is available concerning this phenomenon in diverse species. Additionally, brain tissue uptake of substituted amphetamines is much greater in rats than in humans,¹⁰⁵ suggesting rats could be more sensitive than humans to the effects of MDMA, rather than vice versa. Collectively, the available information indicates that allometric scaling can be used to extrapolate *physiological* variables across species, but this method cannot be used to predict idiosyncratic distribution and metabolism of exogenously administered MDMA in a given animal model.

6.7.4.2 Effect Scaling and MDMA Dosing Regimens

The limitations of allometric scaling led us to investigate the method of “effect scaling” as an alternative strategy for matching equivalent doses of MDMA in rats and humans. In this approach, the lowest dose of drug that produces specific pharmacological responses is determined for rats and humans, and subsequent dosing regimens in rats are calculated with reference to the predetermined threshold dose. Table 6.7.4 shows the doses of MDMA that produce comparable CNS effects in rats and humans. Remarkably, the findings reveal that doses of MDMA in the range of 1 to 2 mg/kg produce pharmacological effects that are equivalent in both species.

Administration of MDMA at doses of 1 to 3 mg/kg causes marked elevations in extracellular 5-HT and DA in rat brain, as determined by *in vivo* microdialysis.^{33,34,39} Although it is impossible to directly measure 5-HT and DA release in living human brain, clinical studies indicate that subjective effects of MDMA (1.5 mg/kg, p.o.) are antagonized by SSRIs, suggesting the involvement of transporter-mediated release of 5-HT.^{1,106} Nash et al.⁴³ showed that i.p. injections of 1 to 3 mg/kg of MDMA stimulate prolactin and corticosterone secretion in rats, and similar oral doses increase plasma prolactin and cortisol in human drug users.^{11,12} The dose of MDMA discriminated by rats and humans is identical: 1.5 mg/kg, i.p., for rats^{107,108} and 1.5 mg/kg, p.o., for humans.¹⁰⁹ Schenk et al.¹¹⁰ demonstrated that rats can be trained to self-administer MDMA using i.v. doses ranging

Table 6.7.4 Comparative Neurobiological Effects of MDMA Administration in Rats and Humans

CNS Effect	Dose in Rats	Dose in Humans
<i>In vivo</i> release of 5-HT and DA	2.5 mg/kg, i.p., Gudelsky et al. ³³ 1 mg/kg, s.c., Kankaanpää et al. ³⁴	*1.5 mg/kg p.o., Leitch et al. ^{1,106}
Secretion of prolactin and glucocorticoids	1–3 mg/kg, i.p., Nash et al. ⁴³	125 mg, p.o., Mas et al. ¹¹ 1.5 mg/kg, p.o., Harris et al. ¹²
Drug discrimination	1.5 mg/kg, i.p., Schechter ¹⁰⁸ 1.5 mg/kg, i.p., Glennon and Higgs ¹⁰⁷	1.5 mg/kg, p.o., Johanson et al. ¹⁰⁹
Drug self-administration	1 mg/kg, i.v., Schenck et al. ¹¹⁰	**1–2 mg/kg, p.o., Tancer and Johanson ¹¹¹

* Subjective effects were attenuated by 5-HT uptake blockers, suggesting the involvement of transporter-mediated 5-HT release.

** Reinforcing effects were determined based on a multiple choice procedure.

from 0.25 to 1.0 mg/kg, indicating these doses possess reinforcing efficacy. Tancer and Johanson¹¹¹ reported that 1 and 2 mg/kg doses of MDMA have reinforcing properties in humans that resemble those of (+)-amphetamine. The findings summarized in Table 6.7.4 indicate there is no need to use interspecies scaling to “adjust” MDMA doses between rats and humans.

Based on this analysis, we devised a repeated MDMA dosing regimen in rats to mimic a one-time recreational binge in humans. Male rats weighing 300 to 350 g served as subjects and were double-housed in plastic shoebox cages. In our initial studies, 3 i.p. injections of 1.5 or 7.5 mg/kg MDMA were administered, one dose every 2 h, to yield cumulative doses of 4.5 or 22.5 mg/kg, respectively. Control rats received saline vehicle according to the same schedule. Rats were removed from their cages to receive i.p. injections, but were otherwise confined to their home cages. The 1.5 mg/kg dose was used as a low “behavioral” dose whereas the 7.5 mg/kg dose was used as a high “noxious” dose (i.e., a dose fivefold greater than threshold). Our repeated dosing regimen was designed to account for the common practice of sequential dosing (i.e., “bumping”) used by human subjects during rave parties. During the MDMA dosing procedure, rectal temperatures were recorded and 5-HT-mediated behaviors were scored every hour. Rats were decapitated 2 weeks after dosing, brain regions were dissected, and tissue levels of 5-HT and DA were determined by HPLC-ECD as described previously.¹¹²

Data in Figure 6.7.7 illustrate that repeated i.p. doses of 7.5 mg/kg MDMA elicit persistent hyperthermia on the day of treatment, whereas repeated doses of 1.5 mg/kg do not. As shown in Figure 6.7.8, high-dose MDMA treatment produces long-term depletions of tissue 5-HT in a number of brain regions (~50% reductions), but the low-dose group displays 5-HT concentrations similar to saline controls. Transmitter depletion is selective for 5-HT neurons since tissue DA levels are unaffected. The magnitude of 5-HT depletions depicted in Figure 6.7.8 is similar to that observed by others.^{67–70} Our findings demonstrate that repeated injections of MDMA at a threshold behavioral dose do not cause acute hyperthermia or long-term 5-HT depletions. In contrast, repeated injections of MDMA at a dose that is fivefold higher than the behavioral dose induce both of these adverse effects. The data are consistent with those of O’Shea et al.¹¹³ who reported that high-dose MDMA (10 or 15 mg/kg, i.p.), but not low-dose MDMA (4 mg/kg, i.p.), causes acute hyperthermia and long-term 5-HT depletion in Dark Agouti rats. Thus, our data confirm that acute hyperthermia produced by MDMA is an important factor contributing to the mechanism underlying subsequent long-term 5-HT depletion.

6.7.5 Consequences of MDMA-Induced 5-HT Depletions

As noted above, high-dose MDMA administration causes persistent inactivation of tryptophan hydroxylase, which leads to inhibition of 5-HT synthesis and long-term loss of 5-HT.^{70,72} Moreover, MDMA-induced reduction in the density of SERT binding sites leads to decreased capacity for uptake of [³H]5-HT in nervous tissue.^{67–69} Regardless of whether these deficits reflect neurotoxic

Figure 6.7.7 Acute effects of MDMA on core body temperature in rats. Male rats received three sequential i.p. injections of 1.5 or 7.5 mg/kg MDMA, one dose every 2 h (i.e., injections at 0, 2, and 4 h). Saline was administered on the same schedule. Core temperature was recorded via a rectal thermometer probe every 2 h. Data are mean \pm SEM expressed as degrees Celsius for $N = 5$ rats/group. *Significant with respect to saline-injected control at each time point ($P < 0.05$ Duncan's).

Figure 6.7.8 Long-term effects of MDMA on tissue levels of 5-HT (left panel) and DA (right panel) in brain regions. Male rats received three i.p. injections of 1.5 or 7.5 mg/kg MDMA, one dose every 2 h. Saline was administered on the same schedule. Rats were killed 2 weeks after injections, brain regions were dissected, and tissue 5-HT and DA were assayed by HPLC-ECD.¹¹² Data are mean \pm SEM expressed as percent of saline-treated control values for each region, $N = 5$ rats/group. Control values of 5-HT and DA were 557 ± 24 and 28 ± 4 pg/mg tissue for frontal cortex (CTX), 429 ± 36 and $10,755 \pm 780$ pg/mg tissue for striatum (STR), and 1174 ± 114 and 4545 ± 426 pg/mg tissue for olfactory tubercle (OT). * Significant compared to saline-injected control for each region ($P < 0.05$ Duncan's).

damage or long-term adaptation, such changes would be expected to have discernible *in vivo* correlates. Many investigators have examined functional consequences of high-dose MDMA administration, and a comprehensive review of this subject is beyond the scope of the present review.⁴⁸ Nonetheless, the following discussion will consider long-term effects of MDMA (i.e., >2 weeks) on *in vivo* indicators of 5-HT function in rats, as measured by microdialysis sampling, neuroendocrine secretion, and specific aspects of behavior. A number of key findings are summarized in Table 6.7.5. In general, few published studies have been able to relate the magnitude of MDMA-induced 5-HT depletion to the degree of specific functional impairment. MDMA administration rarely causes persistent changes in baseline measures of neural function, and deficits are most readily demon-

Table 6.7.5 Long-Term Effects of MDMA on Functional Indices of 5-HT Transmission in Rats

strated by provocation of the 5-HT system by pharmacological (e.g., drug challenge) or physiological means (e.g., environmental stress).

6.7.5.1 *In Vivo* Microdialysis Studies

In vivo microdialysis has been used to evaluate the persistent neurochemical consequences of MDMA exposure in rats.^{88,114–116} Series et al.¹¹⁴ carried out microdialysis in rat frontal cortex 2 weeks after a 4-day regimen of 20 mg/kg s.c. MDMA. Prior MDMA exposure did not affect baseline extracellular levels of 5-HT, but decreased levels of the 5-HT metabolite, 5-hydroxyindoleacetic acid (5-HIAA), to ~30% of control. Moreover, the ability of (+)-fenfluramine to evoke 5-HT release was markedly blunted in MDMA-pretreated rats. In an analogous investigation, Shankaran and Gudelsky¹¹⁵ assessed neurochemical effects of acute MDMA challenge in rats that had previously received 4 doses of 10 mg/kg i.p. MDMA. A week after MDMA pretreatment, baseline levels of dialysate 5-HT and DA in striatum were not altered even though tissue levels of 5-HT were depleted by 50%. The ability of MDMA to evoke 5-HT release was severely impaired in MDMA-pretreated rats while the concurrent DA response was normal. In this same study, effects of MDMA on body temperature and 5-HT syndrome were attenuated in MDMA-pretreated rats, suggesting drug tolerance.

Taken together, the microdialysis data reveal several important consequences of MDMA administration: (1) baseline levels of dialysate 5-HT are unaltered, despite depletion of tissue indoles, (2) baseline levels of dialysate 5-HIAA are consistently decreased, and (3) stimulated release of 5-HT is blunted in response to pharmacological or physiological provocation. The microdialysis findings in MDMA-pretreated rats resemble those obtained with 5,7-DHT, in which drug-pretreated rats display normal baseline extracellular 5-HT but decreased 5-HIAA.^{117–119} In a representative study, Kirby et al.¹¹⁷ performed microdialysis in rat striatum 4 weeks after intracerebroventricular 5,7-DHT. These investigators found that reductions in baseline dialysate 5-HIAA and impairments in stimulated 5-HT release are highly correlated with the degree of tissue 5-HT depletion, whereas baseline dialysate 5-HT is not. In fact, depletions of brain tissue 5-HT up to 90% did not affect baseline levels of dialysate 5-HT. Clearly, adaptive mechanisms serve to maintain normal concentrations of synaptic 5-HT, even under conditions of severe transmitter depletion. A comparable situation exists after lesions of the nigrostriatal DA system in rats where baseline levels of extracellular DA are maintained in the physiological range despite substantial loss of tissue DA.¹²⁰ In the case of high-dose MDMA treatment, it seems feasible that reductions in 5-HT uptake (e.g.,

less functional SERT protein) and metabolism (e.g., decreased monoamine oxidase activity) can compensate for 5-HT depletions in order to keep optimal concentrations of 5-HT bathing nerve cells. On the other hand, deficits in the ability to release 5-HT are readily demonstrated in MDMA-pretreated rats when 5-HT systems are taxed by drug challenge or stressors.

6.7.5.2 Neuroendocrine Challenge Studies

5-HT neurons projecting to the hypothalamus provide stimulatory input for the secretion of adrenocorticotropin (ACTH) and prolactin from the anterior pituitary.¹²¹ Accordingly, 5-HT releasers (e.g., fenfluramine) and 5-HT receptor agonists increase plasma levels of these hormones in rats and humans.¹²² Neuroendocrine challenge experiments have identified changes in serotonergic responsiveness in rats treated with MDMA.^{123–125} In the most comprehensive study, Poland et al.¹²⁵ examined effects of high-dose MDMA on hormone responses elicited by acute fenfluramine challenge. Rats received injections of 20 mg/kg s.c. MDMA and were tested 2 weeks later. Prior MDMA exposure did not alter baseline levels of circulating ACTH or prolactin. However, in MDMA-pretreated rats, fenfluramine-induced ACTH secretion was reduced while prolactin secretion was enhanced. The MDMA dosing regimen caused significant depletions of tissue 5-HT in various brain regions, including hypothalamus. In a follow-up time-course study, rats exposed to multiple doses of 20 mg/kg MDMA displayed blunted ACTH responses that persisted for 12 months, even though tissue levels of 5-HT were not depleted at this time point. The data show that high-dose MDMA can cause functional abnormalities for up to 1 year, and such changes are not necessarily coupled to 5-HT depletions.

In our laboratory, we wished to further explore the long-term neuroendocrine consequences of MDMA administration. Utilizing the “effect scaling” regimen described previously, male Sprague-Dawley rats received 3 i.p. injections of 1.5 or 7.5 mg/kg MDMA, one dose every 2 h. Control rats received saline vehicle according to the same schedule. A week after MDMA treatment, rats were fitted with indwelling jugular catheters under pentobarbital anesthesia. After 1 week of recovery from surgery (i.e., 2 weeks after MDMA or saline), rats were brought into the testing room, i.v. doses of 1 and 3 mg/kg MDMA were administered, and blood samples were withdrawn. Plasma levels of corticosterone and prolactin were measured by radioimmunoassay methods.¹²⁶ The data depicted in Figure 6.7.9 show that MDMA pretreatment did not alter baseline levels of either hormone. Acute

Figure 6.7.9 Effects of MDMA pretreatment on secretion of corticosterone (left panel) and prolactin (right panel) evoked by acute MDMA challenge. Male rats received three i.p. injections of 1.5 or 7.5 mg/kg MDMA, one dose every 2 h. Saline was administered on the same schedule. Then 2 weeks later rats received i.v. injections of 1 and 3 mg/kg MDMA. Blood samples were drawn via indwelling catheters; plasma corticosterone and prolactin were measured by RIA.¹²⁶ Data are mean \pm SEM, expressed as ng/ml of plasma for $N = 8$ rats/group. Baseline corticosterone and prolactin levels were 73 ± 18 and 2.4 ± 0.6 ng/ml of plasma, respectively. *Significant compared to saline-pretreated control group ($P < 0.05$ Duncan's).

administration of MDMA elicited dose-dependent elevations in circulating corticosterone and prolactin as shown by others.⁴³ Rats exposed to high-dose MDMA pretreatment displayed significant reductions in corticosterone and prolactin secretion in response to acute MDMA challenge, whereas hormone responses in the low-dose MDMA rats were indistinguishable from controls.

Our neuroendocrine results are consistent with the development of tolerance to hormonal effects of MDMA. These findings do not agree completely with the data of Poland et al.¹²⁵ discussed above. However, our findings are consistent with previous data showing blunted hormonal responses to fenfluramine in rats with fenfluramine-induced 5-HT depletions.¹²⁶ Perhaps more importantly, the data shown in Figure 6.7.9 are strikingly similar to clinical findings in which cortisol and prolactin responses to acute (+)-fenfluramine administration are reduced in human MDMA users.^{85,127,128} Indeed, Gerra et al.¹²⁸ reported that (+)-fenfluramine-induced prolactin secretion is blunted in abstinent MDMA users for up to 1 year after cessation of drug use. The mechanism(s) underlying altered sensitivity to (+)-fenfluramine and MDMA are not known, but it is tempting to speculate that MDMA-induced impairments in evoked 5-HT release are involved, as shown by *in vivo* microdialysis studies. While some investigators have cited neuroendocrine changes in human MDMA users as evidence for 5-HT neurotoxicity, Gouzoulis-Mayfrank et al.⁸⁵ provide a compelling argument that endocrine abnormalities in MDMA users could be related to cannabis use rather than MDMA. Further experiments will be required to resolve the precise nature of neuroendocrine changes in MDMA users.

6.7.5.3 Behavioral Assessments

One of the more serious and disturbing clinical findings is that MDMA causes persistent cognitive deficits in human users.^{7,8,87} Numerous studies have examined the effects of MDMA treatment on learning and memory in rats, and most studies failed to identify persistent impairments — even when extensive 5-HT depletions were present.^{45,129–133} While an exhaustive review of this literature is not possible here, representative findings will be mentioned. In an extensive series of experiments, Seiden et al.¹²⁹ evaluated the effects of high-dose MDMA on a battery of tests including open-field behavior, schedule-controlled behavior, one-way avoidance, discriminated two-way avoidance, forced swim, and radial maze performance. Male rats received twice daily s.c. injections of 10 to 40 mg/kg MDMA for 4 days, and were tested beginning 2 weeks after treatment. Despite large depletions of brain tissue 5-HT, MDMA-pretreated rats exhibited normal behaviors in all paradigms. Likewise, Robinson et al.¹³⁰ found that MDMA-induced depletion of cortical 5-HT up to 70% did not alter spatial navigation, skilled forelimb use, or foraging behavior in rats. In contrast, Marston et al.¹³⁴ reported that MDMA administration produces persistent deficits in a delayed non-match to performance (DNMTP) procedure when long delay intervals are employed (i.e., 30 s). The authors theorized that delay-dependent impairments in the DNMTP procedure reflect MDMA-induced deficits in short-term memory consolidation, possibly attributable to 5-HT depletion.

With the exception of the findings of Marston et al., the collective behavioral data in rats indicate that MDMA-induced depletions of brain 5-HT have little or no effect on cognitive processes. There are several potential explanations for this apparent paradox. First, high-dose MDMA administration produces only partial depletion of 5-HT in the range of 40 to 60% in most brain areas. This level of 5-HT loss may not be sufficient to elicit behavioral alterations, as compensatory adaptations in 5-HT neurons could maintain normal physiological function. Second, MDMA appears to selectively affect fine diameter fibers arising from the dorsal raphe, and it seems possible that these 5-HT circuits may not subserve the behaviors being monitored. Third, the behavioral tests utilized in rat studies might not be sensitive enough to detect subtle changes in learning and memory processes. Finally, the functional reserve capacity in the CNS might be sufficient to compensate for even large depletions of a single transmitter.

While MDMA appears to have few long-term effects on cognition in rats, a growing body of evidence demonstrates that MDMA administration can cause persistent anxiety-like behaviors in

this species.^{135–137} Morley et al.¹³⁵ first reported that MDMA induces long-term anxiety in male rats. These investigators administered one or 4 i.p. injections of 5 mg/kg MDMA on 2 consecutive days, then tested rats 3 months later in a battery of anxiety-related paradigms including elevated plus maze, emergence, and social interaction tests. Rats receiving single or multiple MDMA injections displayed marked increases in anxiogenic behaviors in all three tests. In a follow-up study, Gurtman et al.¹³⁶ replicated the original findings of Morley et al. using rats pretreated with 4 i.p. injections of 5 mg/kg MDMA for 2 days — persistent anxiogenic effects of MDMA were associated with depletions of 5-HT in the amygdala, hippocampus, and striatum. Interestingly, Fone et al.¹³⁷ showed that administration of MDMA to adolescent rats caused anxiety-like impairments in social interaction, even in the absence of 5-HT depletions or reductions in [³H]-paroxetine-labeled SERT binding sites. These data suggest that MDMA-induced anxiety does not require 5-HT deficits.

In an attempt to determine potential mechanisms underlying MDMA-induced anxiety, McGregor et al.¹³⁸ evaluated effects of the drug on anxiety-related behaviors and a number of post-mortem parameters including autoradiography for SERT and 5-HT receptor subtypes. Rats received moderate (5 mg/kg, i.p., 2 days) or high (5 mg/kg, i.p., 4 injections, 2 days) doses of MDMA, and tests were conducted 10 weeks later. This study confirmed that moderate doses of MDMA can cause protracted increases in anxiety-like behaviors without significant 5-HT depletions. Furthermore, the autoradiographic analysis revealed that anxiogenic effects of MDMA may involve long-term reductions in 5-HT_{2A/2C} receptors rather than reductions in SERT binding. Additional work by Bull et al.^{139,140} suggests that decreases in the sensitivity of 5-HT_{2A} receptors, but not 5-HT_{2C} receptors, could underlie MDMA-associated anxiety. Clearly, more investigation into this important area of research is warranted.

6.7.6 Conclusions

The findings reviewed here allow a number of tentative conclusions to be made with regard to MDMA neurobiology. (1) MDMA is a substrate for monoamine transporters, and non-exocytotic release of 5-HT, NE, and DA underlies pharmacological effects of the drug. While MDMA is often considered a selective serotonergic agent, many actions including cardiovascular stimulation and hyperthermia likely involve NE and DA mechanisms. (2) MDMA produces long-term changes in 5-HT neurons, as exemplified by sustained depletions of forebrain 5-HT in rats. Emerging evidence indicates that 5-HT deficits are not synonymous with neuronal damage, however, since doses of MDMA that cause marked 5-HT depletions (e.g., 10 to 20 mg/kg) are not associated with cell death, silver-positive staining, or reactive gliosis. Like many other psychotropic agents, MDMA is capable of producing *bona fide* neurotoxicity at sufficient doses (e.g., >30 mg/kg) and damage is not confined to 5-HT neurons. (3) There appears to be no scientific rationale for using interspecies scaling to adjust doses of MDMA between rats and humans because behaviorally active doses are similar in both species (e.g., 1 to 2 mg/kg). Nonetheless, the complex metabolism of MDMA needs to be examined in various animal species to permit comparison with clinical literature and to validate appropriate preclinical models. (4) MDMA-induced 5-HT depletions in rats are accompanied by abnormalities in evoked 5-HT release, neuroendocrine secretion, and specific behaviors. The clinical relevance of preclinical findings is uncertain, but the fact that MDMA can produce persistent increases in anxiety-like behaviors in rats without measurable 5-HT deficits suggests even moderate doses may pose risks.

INTRODUCTION

Substance misuse is often considered to be an unpopular subject with many doctors, partly because of the frequent relapse experienced by addicts and partly because of the behavioral problems that can occur when drug users interact with substance misuse treatment services.

Many clinical drug treatment services are dominated by the prescribing of methadone to those dependent on heroin (diacetylmorphine). Methadone maintenance treatment (MMT) has been the most rapidly expanded treatment for heroin dependence over the last 30 years with increasingly large numbers of countries providing such treatment for extensive treatment populations. Even more recently buprenorphine, a partial agonist, has been introduced into drug treatment services and has provided an alternative to methadone. Many doctors involved with addiction problems will see themselves as having only a prescribing role whereas specialists in the field will, in addition, require a repertoire of psychotherapy skills.

Prescribing for patients who may have a dependence on a number of drugs, who may wish to conceal the extent of their substance use, and who may have a marked tolerance to some classes of drug is discussed in order to help inform the practitioner.

This chapter is divided into six sections, mainly intended to provide an overview for the non-specialist. The first section explains the psychology of addiction, as opposed to the neurochemistry of addiction discussed in Chapter 6. Overviews are provided of substitute prescribing, an increasingly accepted practice. Considerable discussion is devoted to the identification and management of withdrawal syndromes, whether sedative or stimulant. The final section briefly discusses toxicological testing, primarily for the purpose of assessing compliance. Additional information on this subject can be found in Chapters 1, 3, and 11.

7.1 THE PRINCIPLES OF ADDICTION MEDICINE

Duncan Raistrick, M.B.B.S.

The Leeds Addiction Unit, Leeds, U.K.

Many doctors involved with addiction problems will see themselves as having only a prescribing role whereas specialists in the field will, in addition, require a repertoire of psychotherapy skills.

Prescribing for patients who may have a dependence on a number of drugs, who may wish to conceal the extent of their substance use, and who may have a marked tolerance to some classes of drug presents difficulties for the unwary or ill-informed doctor. In order to prescribe safely and effectively doctors must:

1. Understand the nature of dependence
2. Understand the dependence-forming potential of drugs
3. Understand the importance of motivation

7.1.1 Understanding the Nature of Dependence

In the U.K. and North America, the understanding of addiction has been dominated by the disease theory and the social learning theory. Heather¹ succinctly describes the history and development of thinking underpinning these theories. Other theories or, perhaps more correctly, models of addiction have been popular in particular cultures or where partial explanations have utility; for example, psychoanalytical interpretations of addictive behavior are common in some European countries, and equally, religious or moral failures are attractive reasons to account for addictive behavior where spiritual values are important as in many Asian and Indian communities.

The important implications of the disease theory depend on the notion that addiction is caused by some irreversible deficiency or pathology and that treatment is, therefore, primarily a medical concern. Certain conclusions inevitably follow from such a premise: (1) abstinence is the only treatment goal, (2) loss of control is the hallmark feature, (3) patients are not responsible for their illness, (4) therapists tend to be medical practitioners, and, finally, (5) community-based prevention will be ineffective.

In formulating a description of alcohol and later other drug dependence, Edwards and Gross² argued against the disease model in favor of a biopsychosocial construction of dependence, which was identified as belonging to a separate dimension from substance-related harms. This formulation has been adopted in the International Classification of Diseases, ICD-10.³ The important implications of social learning theory are: a range of treatment goals is possible, the ability to control substance use is emphasized, users are active participants in treatment, therapists tend to be nonmedical, and fiscal and other control measures will be effective.

The biopsychosocial description of dependence has been criticized for placing unwarranted emphasis on withdrawal symptoms. While the anticipation or experience of withdrawal may indeed be a potent source of negative reinforcement for drinking, it is not the only source of reinforcement, and it may be that the positive reinforcement of a pharmacological (drug) effect is more important whether or not an individual also experiences withdrawal. To take account of this, Raistrick et al.⁴ have proposed a modified description of the dependence syndrome and developed the idea of substance dependence as a purely psychological phenomenon where tolerance and withdrawal are understood as consequences of regular drinking, rather than being a part of dependence. The withdrawal symptoms themselves are one step removed from the cognitive response to the symptoms, which may or may not include thoughts about drinking. If withdrawal symptoms were themselves a defining element of dependence, then different drugs would be associated with different kinds of dependence, but this is not a widely held view. Rather, it is believed that dependence can readily shift from one substance to another.⁵ The markers of substance dependence translate the neuroadaptive elements of the biopsychosocial description of dependence into cues that condition cognitions and behaviors and are therefore of more universal application. There are ten markers of substance dependence:

1. Preoccupation with drinking or taking drugs
2. Salience of substance use behavior
3. Compulsion to start using alcohol or drugs
4. Planning alcohol- or drug-related behaviors

5. Maximizing the substance effect
6. Narrowing of substance use repertoire
7. Compulsion to continue using alcohol and drugs
8. Primacy of psychoactive effect
9. Maintaining a constant state (of intoxication)
10. Expectations of need for substance use

In summary, the most complete account of addictive behaviors comes from a synthesis of physiology, pharmacology, psychology, sociology, and social learning. Dependence exists along a continuum of severity implying the need for different treatments and outcome goals. Substance-related harms in physical, psychological, and social spheres belong to a separate domain. *Addiction* has become a term without precise meaning, but is generally taken to include dependence, problem use, and any related harms. While social learning allows that anyone may become dependent on psychoactive substances and may also unlearn their dependence, it does not preclude the possibility that substance use may cause deficiencies of endogenous neurotransmitters, which are usually reversible, or permanent damage to receptor structure and connectivity. Indeed, it is likely that such changes occur.

7.1.2 Understanding the Dependence-Forming Potential of Drugs

7.1.2.1 Potency of Psychoactive Effect

In humans, the reinforcing properties of psychoactive substances, which combine to generate the umbrella construct dependence, are complex: a prominent view attaches importance to the positive reinforcing effects of inducing pleasurable mood states and the negative reinforcement of avoiding painful affects. Pervin⁵ explores this very issue in a study of four polydrug users: subjects were asked to describe situations (1) where they wanted to use drugs, (2) after they had used drugs, (3) where they wanted to use drugs but could not, and (4) unrelated to drug use, and then to associate affects from a prepared list with the four situations they described. A factor analysis produced three factors accounting for 44% of the variance: the first factor, Wish, was characterized as being tense, helpless, jittery, lonely; the second factor, After Drugs, was characterized as lonely, empty, inhibited, angry; and the third factor, Taking Drugs, included confidence, relaxed, high, secure, strong, satisfied. The results also indicated that subjects discriminated between drugs suited to dealing with different effects.

In two complementary reports, Johanson and Uhlenbuth^{6,7} compared changes in mood among normal volunteers in a choice experiment between placebo, diazepam, and amphetamine. Amphetamine 5 mg was chosen significantly more often than placebo, 81% of possible choices, with increased scores for vigor, friendliness, elation, arousal, positive mood, and decreased scores for confusion. In contrast, diazepam 5 and 10 mg were chosen significantly less often than placebo, 28 and 27% of choices, respectively, with decreased scores on vigor and arousal and increased scores on confusion and fatigue. The point to underline here is that normal subjects are likely to have different effects to patient groups and the reinforcing potential of different substances will therefore vary between such groups: within matched subjects the reinforcing properties of different substances will also vary in strength.

At a clinical level, most doctors are wary of addictive drugs: for example, long-term methadone prescribing is intended to achieve pharmacological stability, at least partially block the effect of other opioids, and prevent withdrawal symptoms. However, Bickel et al.⁸ suggest that, although methadone is seen as a low tariff drug, treatment retention is, in part, associated with its reinforcing properties. Using a choice paradigm, subjects maintained on methadone 50 mg daily, identified to subjects as capsule A, had the option of taking capsule B, which, in different trials, contained either methadone 50, 60, 70, or 100 mg, in place of Capsule A. Capsule B was chosen on 50, 73, 87, and 97%, respectively, of occasions: at the highest dose, subjects identified an opioid effect and a

liking for the drug but no high or withdrawal was reported. The clinical implications are quantified by McGlothlin and Anglin⁹ in a 7-year follow-up of patients attending high- vs. low-dose methadone maintenance programs: the high-dose program performed better in terms of retention, significantly fewer arrests and periods of incarceration, less criminal activity, and less supplementary drug use. In a similar type of study, Hartnoll et al.¹⁰ followed up addicts randomly allocated to an injectable heroin or oral methadone program: at 1-year follow-up, 74% of the heroin group against 29% of the methadone group were still in treatment but only 10% against 30% had achieved abstinence from illicit drugs. So, the dilemma is that prescriptions most liked by addicts, namely, those that are more reinforcing, achieve good program retention and a degree of stability, but at the cost of slowing movement away from substance use and the associated subculture.

The potency of psychoactive effect is not simply a function of dose or plasma level, but also depends on receptor uptake characteristics. For example, Chiang and Barnett¹¹ have shown that immediately after intravenous tetrahydrocannabinol a rising plasma concentration of approximately 45 ng/ml relates to a subjective high of 10% whereas the same falling plasma concentration 15 min later relates to a high of nearly 80% on a self-rating 0 to 100% scale. This phenomenon is accounted for by a slow uptake of THC at the receptors. Active metabolites may spuriously suggest the same phenomenon.

Similarly, the partial agonist buprenorphine has a high, but slow, binding affinity at the opiate mu receptor: it has the potential to act as antagonist against pure opioid agonists and itself appears to have a ceiling effect at about 1 mg subcutaneously for subjective response. Although addicts identify buprenorphine as having an opioid effect and therefore potential for misuse, its binding affinity at the mu receptor and antagonist activity confer a quite different reinforcement profile to pure agonists such as diamorphine (heroin).

The clinical significance is demonstrated by Johnson et al.¹² who substituted heroin for buprenorphine in ascending daily doses of 2, 4, and 8 mg: using this regimen, diamorphine withdrawal symptoms were avoided and, overall, subjects reported a feeling of well-being. Withdrawal from buprenorphine 8 mg daily does not precipitate an opiate withdrawal syndrome.

7.1.2.2 Pharmacokinetics

The previous section argued that the mood-altering effects of psychoactive drugs may, depending on the pre-drug mental state, have both positive and negative reinforcing properties. Psychoactive effect alone is insufficient explanation of within-drug-group differences of dependence forming potential: different pharmacokinetics is important. The benzodiazepines and opioids are the most fruitful source of investigation here because both drug groups contain many different compounds that are widely used and misused. However, it is difficult to conduct studies that control for confounding factors such as absorption rate, potency, purity, half-life, or street availability (and likelihood of supplementing). It is perhaps not surprising that researchers are parsimonious with conclusions.

There are ethical problems in conducting laboratory experiments with potent drugs such as heroin and to avoid this problem Mello et al.¹³ investigated the reinforcing efficacy in primates for three opioids: they found buprenorphine and methadone to have similar strength but heroin to be more powerful. Equally in humans heroin is preferred to other opiates including morphine.¹⁴ Since heroin is converted to morphine within the central nervous system (CNS), it can be concluded that its faster rate of CNS availability accounts for the difference. Absorption rate and, therefore, immediacy of effect have similarly been shown to be important for benzodiazepines. Funderburk et al.¹⁵ compared the effects of equipotent oral doses of lorazepam (0, 1.5, 3, and 6 mg) and diazepam (0, 10, 20, and 40 mg) in recreational benzodiazepine users: the drug liking ratings were similar for both drugs, suggesting that the absorption rate, which is similar for the two drugs, is more important than the elimination half-life, which is much shorter for lorazepam even though subjective ratings of effect persist much longer for this compound. Learning theory predicts the

importance of absorption rate in that the most immediate positive consequence of a behavior (drug taking) is the most reinforcing. While potency and the speed of onset of effect are particularly important for initiating dependence, elimination rate assumes greater importance in building and maintaining dependence. As a rule, the more quickly a drug is metabolized, the sooner the user experiences a loss of effect and possibly also withdrawal symptoms. Both of these consequences become cues for further drug use.

7.1.2.3 Plasticity

Plasticity is defined as the degree to which the effect of a drug is independent of internal environment (e.g., mood, thirst) and external environment (e.g., with friends, comfort). Edwards¹⁶ has described substances as existing along a continuum: highly plastic substances, that is, those where the content of the effect is markedly influenced by environment, exist at one end (e.g., solvents, LSD), and substances with very predictable content (e.g., heroin, cocaine) exist at the opposite end. Plasticity has a bearing on the dependence-forming potential of substances; where the content of a drug effect is uncertain, repeated use is unlikely. In contrast, a very predictable effect may not suit the variety of uses demanded of a recreational substance, but yet be powerfully reinforcing, that is, addictive. It is interesting that the most popular recreational drugs, alcohol and cannabis, fall around the middle of the plasticity continuum, perhaps signaling a point that allows an agreeable interaction between drug and expectation effects. In summary, the dependence-forming potential of a drug is a function of:

1. Potency of effect
2. Speed of entering the CNS
3. Speed of joining with receptors
4. Elimination rate
5. Predictability of effect

7.1.3 Understanding the Importance of Motivation

The measurement of dependence and the identification of substance-related problems tell the clinician what outcome goals are likely to be successful and how much treatment is needed; alongside this an understanding of motivation informs what kind of treatment is needed. The Model of Change described by Prochaska and DiClemente¹⁷ is a motivational model widely used in the addiction field. The purpose of using the model is twofold: first, to understand what is going on for a patient at a given time; second, to inform the patient of the choice of interventions. People who are not motivated to change their substance use are said to be at the pre-contemplation stage, which is characterized by denial and rationalization of substance use and its consequences. There are two strands to treatment strategy at this stage: one is to minimize harm without expecting to change the substance use behavior (for example, by giving nutritional supplements or substitute prescribing). The second is to introduce conflict about the substance use (for example, by making links with untoward life events and thereby creating motivation for change). The temptation is to offer treatments aimed at changing substance use behavior before the patient is ready to change. In such circumstances the treatment will always fail.

The experience of significant conflict about substance use (for example, when an arrest is felt to be incompatible with a self-image of being a sensible and responsible person) or when the cost of substance use is causing family hardship indicates movement into the contemplation stage. At this stage, motivational interventions, which may involve the use of simple clinical tools (for example, the decision matrix), or may draw on more sophisticated skills (for example, motivational interviewing),¹⁸ are indicated. At this stage substitute prescribing or agonist prescribing may be helpful.

The action stage is reached when conflict is resolved and there is a commitment to change. A number of things will have happened at a psychological level: the person will believe that life will be better on stopping or controlling their substance use (positive outcome expectancy), they are able to change (self-efficacy), and they will know how to change (skills learning). Elective detoxification is the most common medical intervention at the action stage.

The maintenance stage follows behavioral change. This is the achievement of abstinence or controlled substance use. Maintenance of behavior change for alcohol misuse may be assisted by prescribing a sensitizing agent such as disulfiram or, for opiate misuse, prescribing an antagonist such as naltrexone. Pharmacological interventions are no more than an adjunct to the main task of achieving lifestyle change. Successful exit from the maintenance stage, recovery, requires that the patient has confidence and skills to deal with substance use cues. Achieving the right mix of pharmacology and psychology is more art than science, but an understanding of the underlying brain mechanisms, reviewed for clinicians by Nutt,¹⁹ and a parallel understanding of motivation will help achieve safe and effective prescribing.

7.1.4 Prescribing in Context

Addiction problems are everyone's business: the sociologist, the politician, the biochemist, the doctor, the police officer, the parent, the pharmacist, the taxpayer, the drug dealer, and the public. The list is long; such is the diversity of interests vested in substance use and misuse. Everyone will have opinions about addiction including opinions about what doctors should prescribe. Doctors should seek the widest possible clinical freedom to manage addiction patients and to secure this freedom. It follows that prescribers must be sensitive to the prevailing medicopolitical views on what constitutes good practice. People who misuse substances, particularly illicit substances, may have particularly forceful views about what doctors should prescribe, but these views are likely to change depending on where a person is within his or her addiction career. It follows that prescribers must have an understanding of addictive behaviors and characteristics of addictive substances. The Model of Change (described above) is a simple, commonly used tool that offers a framework for prescribing and other interventions.

For most people who have developed a moderate or severe dependence, pharmacotherapy will, at some time, be an important part of treatment. However, prescribing alone will never be sufficient. It follows that prescribers must have a repertoire of skills, including behavior therapy and psychotherapy or, alternatively, must work with a co-therapist. When working with a co-therapist, the doctor must be satisfied with the reasons for prescribing and take responsibility for the prescription given.

7.1.5 General Precautions

Doctors who are inexperienced in the field of addiction often feel pressured to prescribe beyond their knowledge and skills, and as a result may issue inappropriate prescriptions. In contrast, specialists are likely to be circumspect about the place of pharmacotherapy and especially so when this means prescribing addictive drugs.²⁰ The precautions listed below are applicable to any prescribing; however, patients who misuse both prescribed and illicit drugs are especially at risk, not least because prescriptions are often for potent preparations in doses higher than normally recommended. Doctors may be required to justify their prescribing to a variety of authorities and are more likely to fall afoul of legal action or audit because of precipitate rather than delayed prescribing. Having established the appropriateness of prescribing, the following checklist will ensure the safety of a prescription:

- Prescribe drugs with low dependence-forming potential.
- Prescribe drugs with low injection potential.

Prescribe drugs with low “street value.”

Prescribe inherently stabilizing drugs.

Assess:

- Risk of overdose by patient

- Risk of overdose by others living with patient

- Risk of diversion for profit or misuse

- Risk of failing to control use as prescribed

Assess tolerance before prescribing potentially lethal doses.

Check other prescribed medication.

Check on co-existing medical conditions.

Monitor compliance.

Safety of prescribing needs to be balanced against a regimen that is convenient for the patient and which will therefore achieve the best results in terms of retention and compliance.^{21,22} Before finally giving a prescription, it is crucial to ensure that both the doctor and the patient understand the purpose of the prescription.²³ There should be agreement on how to monitor whether or not the intended purpose is being achieved; if the purpose is not achieved then the prescription should be reviewed and possibly discontinued. This does not imply an end to therapy but rather consideration of a shift to an alternative, possibly nonpharmacological treatment.

7.2 SUBSTITUTE PRESCRIBING

Kim Wolff, Ph.D.

King's College London, Institute of Psychiatry, National Addiction Centre, London, U.K.

Substitute prescribing is the prescription of the main drug of misuse or a drug from the same pharmacological group but of lower dependence potential to a dependent individual. The main purpose of substitute prescribing is to stabilize a person's substance use and offer a period of time to work on non-drug-focused interventions. Slow reduction or detoxification can occur at any time during substitute prescribing. Recipients of substitute prescribing may fall into one or more of the following categories:

1. Diagnosis of opioid, cocaine, amphetamine, or benzodiazepine dependence
2. Minimum 6-month history of regular use
3. Regular injecting, especially if high risk, of whatever duration
4. Failed attempts to achieve abstinence
5. At time of initial assessment, likely to be at the pre-contemplation or contemplation stage of change

Evidenced-based guidelines for providing substitute treatment for drug misusers have been reported^{23–25} and, in brief, aim to bring about:

Short term:

- Attract patients into treatment

- Relieve withdrawal symptoms

Long term:

- Retain in treatment

- Reduce injecting behavior

- Stabilize drug use

- Stabilize lifestyle

Reduce criminal behavior
Reduce human immunodeficiency virus (HIV), HBV, and HBC transmission
Reduce death rate

7.2.1 Opioid-Specific Prescribing

Maintenance prescribing differs from substitute prescribing only in that there is no active effort to bring about change in a person's drug use or psychological state. The majority of clinical drug misuse services are concerned principally with the prescription of methadone to heroin users. American reviews tend to cite methadone as a direct pharmacological treatment in the way that insulin is used for diabetes. Many Europeans, however, would view methadone more as a substitute treatment whereby the improvements that are seen result from removing individuals from the process of using street drugs.²⁴

7.2.1.1 Methadone Maintenance Prescribing

Methadone, a synthetic opioid first reported as a maintenance (long-term, fixed-dose) treatment for opiate dependence by Dole and Nyswander,²⁶ is the most widely used pharmacological treatment for this type of addiction in Britain and North America. Methadone first appeared in Europe in the late 1960s in response to an emerging use of heroin and was officially introduced into Britain in 1968.²⁷ Today methadone remains the preferred drug of choice for the treatment of heroin dependence,²⁸ dominating the substitute prescribing market.²⁹

Substantial evidence exists in the international literature to support the effectiveness of methadone maintenance treatment (MMT), particularly with regard to reduction in intravenous drug misuse,^{30,31} less crime,^{32,33} reemployment,³⁴ social rehabilitation,³⁵ overall health status,³⁴ improved quality of lifestyle,³⁶ and safety and cost effectiveness compared to other (drug-free) alternatives.³⁷ The National Treatment Outcome Research Study (NTORS) reported similar findings in Britain.³⁸ Retention in treatment is the key, however, and discernible treatment effects are only seen when patients remain in treatment for longer than 1 year.³⁹ The available evidence indicates that it is methadone per se that retains patients in treatment.⁴⁰

Following a move toward a harm minimization (rather than abstinence) in response to the perceived threat from the HIV, there was a rapid expansion of methadone treatment in Britain, the U.S., and Australia.⁴¹ Methadone treatment continues to play an important role in the prevention of the transmission of HIV infection among injectors of heroin.^{42,43}

7.2.1.2 Treatment Compliance

Studies of treatment response have shown that patients who comply with the recommended course of treatment have favorable outcomes during treatment and longer-lasting post-treatment benefits. Thus, it is discouraging for many practitioners that opiate users are frequently poorly compliant or noncompliant and subsequently resume substance use.⁴⁴ Insufficient methadone dose has been identified as a major cause of therapeutic failure and relapse to re-abuse drugs,⁴⁰ affecting behavior above and beyond individual differences in motivation and severity of drug dependence.

Despite more than 35 years of clinical use of methadone for the treatment of heroin dependence, appropriate dosing remains controversial. However, a consistent relationship between higher doses of the drug, less illicit opioid use, and retention in treatment has been frequently observed.^{50,51} Previous research indicates that an insufficient dose (inadequate for the prevention of withdrawal symptoms for the total duration of the dosing interval, 24 h) is a major problem for opioid users during treatment.⁵² Unfortunately, the likelihood of success is offset by the fact that many patients do not remain in treatment until they are rehabilitated, and those who drop out usually return (relapse) to drug misuse.⁵³

7.2.1.3 *Therapeutic Drug Monitoring for Methadone*

Many different parameters have been investigated to help assess the efficacy of methadone maintenance treatment. Randomized controlled trials to investigate methadone treatment have been advocated recently.³² A randomized-controlled trial of methadone maintenance treatment in 593 Australian prisoners indicated that heroin use was significantly lower among treated prisoners than control subjects at follow up.^{54,55}

The usual procedure for assessing opioid users at clinics involves urinalysis screening for drugs of abuse (see Chapter 7.6). Urinalysis drug screening is an important way of assessing drug misuse by patients undergoing methadone treatment, but sheds no light on patient compliance, i.e., whether the patient is taking medication as prescribed. It is essential to know if a patient is taking all of their medication (at the correct time and in the correct amount) and to find out whether the patient is using extra methadone (obtained illicitly) or selling some of the prescription, perhaps to other users. Urinalysis will only indicate whether or not a patient has taken some of the medication. Dosage alterations based on interpretation of plasma measurements may help more patients do well on methadone.⁵⁶⁻⁵⁸

Scientific measurements, in addition to urinalysis and report systems, are clearly needed to evaluate patients. It was found that plasma measurements of methadone filled the gap and provided much needed evidence on compliance. Compliance in methadone maintenance patients has been measured using a pharmacological indicator to “estimate” plasma methadone concentrations. The study showed that many patients took their medication haphazardly (incorrect self-administration), whereas others supplemented their dose with illicit methadone.⁵⁹

The success or failure of patients in methadone treatment may be related to the determination of an appropriate daily oral dose,⁶⁰ identifying patients who respond poorly to treatment,⁶¹ and ensuring compliance to the dosage regimen. Such tasks are difficult as clinicians are currently without an accurate, convenient, and objective therapeutic tool for therapeutic drug monitoring.

Blood is the primary biological sample for pharmacokinetic analyses, as both parent and metabolite concentrations can be quantified and samples cannot be adulterated by the donor.⁶² Methadone plasma concentration has been correlated to oral dose when compliance is good^{61,63,64} and plasma methadone concentration can be used to determine an appropriate oral dose.

Studies have reported that there is a robust linear relationship between plasma methadone concentration and oral dose, when patients are on a constant dose, and compliance is good.^{64,65} This relationship can be demonstrated over a wide range of dosages (3 to 100 mg), and the correlation has been reported at $r = 0.89$.⁶⁴

7.2.1.4 *Indications for Plasma Methadone Monitoring*

Take-home methadone: Initially attendance at a methadone dispensing clinic is required on a daily basis to consume medication under staff supervision. This requirement becomes impractical when the patient is assuming responsibility and trying to engage in work, rehabilitation, education programs, or responsible homemaking. Shared-care may be a sensible solution. A collaborative relationship between the prescribing doctor, community pharmacist, and specialist drug treatment center has been advocated as good practice as a means to allow flexibility with prescribing. Unfortunately, the practice of permitting take-home supplies for unsupervised self-administration have contributed problems, including:⁶⁶

1. Accidental ingestion of methadone by nontolerant persons, especially children
2. Methadone toxic reactions
3. Overdose fatalities
4. Diversion for illicit sale

5. Redistribution to other heroin users suffering from withdrawal symptoms
6. Redistribution to drug users seeking a new euphoriant

Monitoring the concentration of methadone in patients who take the drug away from the clinic is advisable to confirm that the prescribed dose is being consumed in the correct amount and at the correct time.

Methadone is metabolized by a specific cytochrome P450 pathway, but as a predominantly oral drug absorption is a prerequisite for its activity. The absorption process is affected by many factors, not least the degree of intestinal first-pass metabolism, which occurs by cytochrome P4503A (CYP3A) and the active extrusion of absorbed drug by the multidrug efflux pump, *P*-glycoprotein (P-gr).

Measuring *N*-demethylation activity or depletion in human liver microsomes and recombinant P450 isoform showed the highest contribution for CYP3A4.^{67,68} However, the metabolism of methadone is complex and has been shown to be subject to *N*-demethylation by CYP2B6, 2C19, 2D6, and 2C9.⁶⁹ Accordingly, CYP3A4 selective inhibitors or monoclonal human anti-CYP3A4 antibodies are able to inhibit the formation of the main metabolic product EDDP by up to 80%,⁷⁰ and CYP3A4 inducers produce a similar reaction in the opposite direction.

Hence many compounds may affect methadone kinetics. Concomitant administration of enzyme-inducing (or inhibiting) drugs is said to be a factor influencing methadone kinetics. Reports suggest that rifampicin,^{71,72} phenytoin,⁷³ barbiturates,⁷⁴ and disulfiram⁷⁵ are associated with unexpectedly low plasma methadone concentrations. Similar effects have been reported with zidovudine (azidothymidine; AZT), fucidic acid,⁷⁶ and amitriptyline,⁷⁷ which are not known enzyme inducers. Reports of the effect of drug inhibitors on the kinetics of methadone are less apparent clinically, but the effect has been demonstrated for fluconazole.⁷⁸ Diazepam appears to inhibit the metabolism of methadone,⁷⁹ but not with therapeutic (<40 mg/day diazepam/day) dosing.⁸⁰ Interaction between methadone and medications used to treat HIV infection are other examples.⁸¹

Physiological state: Other factors said to influence the clearance of methadone include excessive alcohol consumption⁸² and physiological states such as pregnancy.⁸³ To conclude, when compliance is good, plasma methadone concentrations can be used to validate dosing regimes. Conversely, plasma methadone measurements can also be used to assess compliance.

7.2.2 Buprenorphine Maintenance Prescribing

Nick Lintzeris, M.B.B.S., Ph.D.

National Addiction Centre, South London and Maudsley NHS Trust, London, U.K.

Generally, the more efficacious the drug is at producing its pharmacological effect, the greater the addiction potential and value as an illicit drug. Drugs with lower efficacy are called partial agonists. Buprenorphine (BPN) is a partial agonist for opioid receptors. The pharmacological profile of partial agonists is such that they are useful in substitution therapy because they provide some reinforcement of the opiate effect but should also reduce illicit heroin use.

BPN, a derivative of the morphine alkaloid thebaine, is a partial agonist at the μ opiate receptor, resulting in milder, less euphoric, and less sedating opiate effects than full opioid agonists such as heroin, morphine, or methadone. In adequate doses, BPN exerts sufficient opiate effects to diminish cravings for heroin and prevent opiate withdrawal features. BPN also has a high affinity for μ receptors, binding more tightly than full agonists such as heroin or methadone, and through this mechanism reduces the effects of any additional heroin (or other opiate) use.

BPN is also an antagonist at the κ opiate receptor, which may be associated with some antidysphoric^{84–86} and antipsychotic properties⁸⁷ in certain individuals. Further research is required in this area, and BPN is not currently indicated for these conditions.

7.2.2.1 Pharmacokinetics

BPN undergoes extensive first-pass metabolism when taken orally and has more potent effects when injected or taken sublingually. Contemporary preparations in addiction treatment utilize sublingual tablets.* Peak plasma concentrations are achieved 1 to 2 h after sublingual administration. BPN is principally metabolized by two hepatic pathways: conjugation with glucuronic acid and *N*-dealkylation by the CP450 3A4 enzyme system to nor-BPN, an active metabolite that appears not to cross the blood–brain barrier and therefore is of minor clinical importance. Metabolites are excreted in the biliary system with enterohepatic cycling, and the majority of the drug is excreted in feces and urine.

BPN has a relatively short half-life, however, and can exert a considerably longer duration of action, due to its high affinity for μ opiate receptors and its high lipophilicity (accumulation in fat with chronic dosing). Peak effects are described within 1 to 4 h after sublingual administration, with continued effects for up to 12 h at low doses (e.g., 2 mg) to as long as 72 h at higher doses (such as 16 or 32 mg).⁹¹ The prolonged duration at high doses enables alternate day, 3-day, and even 4-day dispensing regimens in many patients.^{88,89}

BPN has an advantageous safety profile due to ceiling dose–response effects, such that high doses (16 mg or more) do not produce substantially greater peak opiate effects than lower doses (8 or 12 mg)⁹⁰ and do not result in significant respiratory depression even in non-opiate-dependent individuals. As with methadone, there are concerns regarding the safety of BPN in combination with other sedatives (alcohol, benzodiazepines), and a number of deaths have occurred under such circumstances. Many patients describe less sedation with BPN than methadone. As with other opiates, constipation, disturbed sleep, drowsiness, headaches, sweating, and nausea are the more common side effects⁹¹ with most side effects subsiding as tolerance develops.

The partial agonist properties of BPN and prolonged duration of action are thought to account for a milder opiate withdrawal syndrome following the cessation of BPN compared to heroin, morphine, or methadone.⁹² The cessation of long-term BPN results in opiate withdrawal peaking 3 to 14 days after cessation, with mild symptoms persisting for weeks. Cessation of short BPN courses (e.g., 1 to 2 weeks) appears to be associated with only minor withdrawal discomfort of several days duration.

Precipitated withdrawal is caused by the high affinity of BPN displacing other opiates (e.g., methadone, heroin) from opiate receptors, but having less opiate activity (partial agonist). This rapid reduction in opiate effects can be experienced as precipitated withdrawal, typically occurring within 1 to 3 h after the first BPN dose, peaking in severity over the first 3 to 6 h, and then subsiding. Precipitated withdrawal is of concern if a patient has recently used heroin (e.g., <6 h previously) or methadone (<24 h previously) prior to his or her BPN dose. Transferring from high-dose methadone (e.g., above 60 mg) to BPN increases the risk of precipitated withdrawal, due to methadone's long duration of action (Table 7.2.1).

Objectively, there was no significant difference between the two groups on measures of opiate withdrawal symptoms. The group receiving alternate-day treatment reported subtle withdrawal symptoms subjectively whereas the daily treatment group reported no such problems.⁹³ A 24-h dosage interval is most commonly recommended. Opiate-dependent subjects find BPN an accept-

* Most studies using sublingual buprenorphine have used a liquid solution in 30% aqueous ethanol. However, commercial sublingual preparations (e.g., Subutex, Suboxone) are tablets with approximately 50% bioavailability of the ethanol solution.

Table 7.2.1 Pharmacological Properties and Clinical Implications of BPN

Pharmacological Property	Clinical Implication
Partial agonist producing mild opiate effects	Reduces cravings for heroin and increases treatment retention
Alleviates opiate withdrawal	Less sedating than full agonists (heroin, morphine, or methadone)
High receptor affinity diminishes the effects of additional opiate use	Can be used for maintenance or detoxification
Long duration of action	Diminishes heroin use
Ceiling dose–response effects	Complicates attempts at analgesia with other opioids (e.g., morphine)
Sublingual preparation	Allows for once-a-day, to three times a week dosing schedules
Comparable affinity for mu receptors to opioid antagonists	Safer in overdose
Side-effect profile similar to other opiates	More time involved in supervised dispensing
	Treatment with naltrexone can be commenced within 24 h of BPN
	Generally well tolerated by heroin users, with most side effects transient

able treatment for their dependence and report a “morphine-like” effect. It is possible to convert people from heroin or methadone to BPN with minimal withdrawal problems.⁹⁴

Due to its wide therapeutic index, BPN is relatively safe in overdose. It has been shown that there is a ceiling effect at higher doses of BPN. This is due to its intrinsic opiate antagonist activity and means that it is possible for a nondependent person to tolerate a single dose of BPN up to 70 times the recommended analgesic dose without life-threatening consequences.⁹⁵ Sublingual preparations have been shown to be as effective as subcutaneous preparations and to have a similar profile of effects in opiate-dependent subjects.⁹⁶

As with methadone, effective BPN maintenance treatment requires regular monitoring and review, structured dispensing arrangements, access to psychosocial services, and long-term treatment retention. A key goal during BPN induction is to prevent precipitated withdrawal, which can usually be achieved by patient education; delaying the first BPN dose until the patient is in mild opiate withdrawal; and commencing with a low first BPN dose (e.g., 4 mg). After ensuring precipitated withdrawal has been averted, the BPN dose should be rapidly titrated upwards, achieving effective doses (e.g., 12 to 24 mg for most patients) within 3 days of commencing treatment. Maintenance BPN doses should be titrated against treatment objectives for each patient. Doses of between 12 and 24 mg/day are often required in order for patients to cease unsanctioned opiate use. Low doses (less than 8 mg/day) are more commonly associated with ongoing heroin use. In treatment settings where BPN dosing is predominately supervised, the frequency of dispensing (and hence inconvenience and costs) can be reduced for most patients by alternate- and 3-day dosing. A dose intended for 48 h interval is approximately twice a daily dose, and a 3-day dose is approximately 2.5 to 3 times a daily dose. Withdrawal from BPN maintenance treatment should only be recommended for stable patients who have ceased substance abuse, are medically, socially, and psychiatrically stable, and who wish to withdraw from maintenance treatment. A gradual reduction over weeks is usually recommended, with 2 mg dose reductions every 2 to 4 weeks as tolerated.

7.2.3 Stimulant Specific

Substitute prescribing for amphetamine usually takes the form of dexamphetamine sulfate tablets whereas there is no obvious alternative for cocaine dependence. However, prescriptions of this kind are only appropriate for a very small minority of patients. It is more likely to be the case that prescribing for stimulant dependence takes the form of an agonist of a different pharmacological group to the main drug of misuse but having its action at the same receptors or in the same neurochemical pathways (replacement prescribing). Typically these agents are used to reduce cravings associated with the cessation of stimulant use. Replacement prescribing is addressed in detail in Chapter 7.4.

7.2.4 Benzodiazepine Specific

Little attention has thus far been paid to the extent to which benzodiazepines are abused primarily as the drug of choice. It seems that benzodiazepines are frequently abused on the illicit drug scene in combination with other drugs, particularly alcohol,⁹⁷ stimulants,⁹⁸ and opiates.⁹⁹ However, there appear to be a number of features that indicate benzodiazepine abuse: two key factors appear to be supra therapeutic dosage to extremely high levels and intermittent binge usage. Substitution prescribing usually takes the form of a long-acting alternative, most commonly diazepam, which has the effect of stabilizing drug use. More recently, chlordiazepoxide has been used to substitute for the benzodiazepine of choice because of its low abuse potential, low street value, and long elimination half-life.

7.2.5 Outcomes for Substitute Prescribing

The Department of Health²³ has selected hierarchies of outcomes for substitute prescribing in the areas of drug use, physical and psychological health, and social functioning, as follows:

Drug use:

1. Abstinence from drugs
2. Near abstinence from drugs
3. Reduction in the quantity of drugs consumed
4. Abstinence from street drugs
5. Reduced use of street drugs
6. Change in drug taking behavior from injecting to oral consumption
7. Reduction in the frequency of injecting

Physical and psychological health:

1. Improvement in physical health
2. No deterioration in physical health
3. Improvement in psychological health
4. Reduction in sharing injection equipment
5. Reduction in sexual risk-taking behavior

Social functioning and life context:

1. Reduction in criminal activity
2. Improvement in employment status
3. Fewer working/school days missed
4. Improved family relationships
5. Improved personal relationships
6. Domiciliary stability/improvement

7.3 TREATMENT OF WITHDRAWAL SYNDROMES

Joanna Banbery, M.B.B.S.

The Leeds Addiction Unit, Leeds, U.K.

7.3.1 Understanding Withdrawal Syndromes

A withdrawal syndrome is the constellation of physiological and behavioral changes that are directly related to the sudden cessation (or reduction in use) of a psychoactive drug to which the body has become adapted. The *Diagnostic and Statistical Manual of the American Psychiatric*

Association in its revised fourth edition (DSM-IV-R)¹⁰⁰ requires three criteria to be fulfilled before a diagnosis of substance withdrawal can be made. For each drug or group of drugs it lists the symptoms and signs that must be present:

Criterion 1: The development of a syndrome (which is substance specific) due to the cessation of or reduction in substance use. The substance use must be heavy and prolonged.

Criterion 2: The withdrawal syndrome must cause clinically significant distress or impairment in social and/or occupational functioning.

Criterion 3: The symptoms caused must not be due to any other medical or mental condition.

Dependence has been discussed in the introduction to this chapter. Withdrawal symptoms were described as a consequence of regular drug use rather than as a fundamental element. On a cellular level, dependent use of a drug will cause a state of adaptation in which the presence of the drug is necessary for normal functioning and in which the removal of the drug will cause some abnormality of function.¹⁰¹ Drug-induced alterations to function include alteration of the fluidity of the cell membrane, or alteration in neurotransmitters and receptor changes. Each group of drugs will produce its own characteristic withdrawal syndrome, which will be dependent on specific alterations to the above systems. These have already been well reviewed.¹⁰²

Although the basis of withdrawal lies in the cellular and receptor changes, it is important not to forget that there is a significant psychological component. Changes at the tissue level give rise to symptoms and signs. These are then interpreted in a way that will depend on a person's situation and expectations about withdrawal together with his or her emotional state. These reactions then feedback and may magnify the original changes or help to reduce them. Psychologists have found that withdrawal symptoms will behave as conditioned responses. They will develop more quickly if associated with a cue and can be evoked by environmental stimuli when the drug has not been used for some time.¹⁰³ This helps to explain why the clinical symptoms presented by patients are very variable both from time to time and place to place. The time it takes to develop a withdrawal effect will depend on the pharmacokinetics of the drug, so that withdrawal from methadone, which has a long half-life, will not become evident for 24 to 36 h, whereas withdrawal from heroin, with a shorter half-life, will occur within 6 to 8 h of the last dose. This is of clinical importance in planning a detoxification.

7.3.1.1 Detoxification

When drug use ceases, the nervous system will begin to undergo a return to normal functioning. During this time, abnormal responses will be evident in the form of withdrawal symptoms, and the patient will be vulnerable both physically and psychologically. Detoxification is the process of rapidly and successfully achieving a drug-free state and will usually involve both the prescription of drugs to attenuate withdrawal symptoms and the attention to the relief of other stressors.

It is an appropriate intervention for those patients who are at the "action" stage of change,¹⁷ that is, those patients who have demonstrated a commitment to change their substance use, believe they are able to change, and have acquired the necessary skills to enable them to sustain change. Detoxification will also be necessary for other patients as an expedience in situations such as emergency hospitalization or rapidly deteriorating mental or physical health.

The goal of achieving abstinence with the minimum amount of discomfort should be agreed upon with the patient. Adequate preparation is essential; the patient must be informed of the expected symptoms, their likely duration, medication that will be used to relieve symptoms and its likely effects. Consideration should be given to the setting for the detoxification. Home, outpatient, or inpatient facilities may all be suitable. The physician and the patient will need to agree upon an environment that is comfortable, nonthreatening, and safe. If the detoxification is to be undertaken at home, there must be confidence that any withdrawal symptoms will not be severe and that adequate support is available.

The appearance of withdrawal symptoms should be carefully monitored with consideration being given to the use of assessment scales.¹⁰⁴ If an outpatient detoxification is being performed the patient may attend on a daily basis for an objective assessment of withdrawal symptoms to be made. The severity of the syndrome will influence the dosage and frequency of medication given to alleviate them. Physicians should have an awareness of which drugs will cause severe or dangerous withdrawal symptoms and may require particularly careful assessment. Increasingly, patients present with polydrug use, which requires extra vigilance and may require adaptations of usual prescribing regimens.

Patients who are to be detoxified will require a thorough medical examination usually with routine blood tests. These patients are at high risk of an underlying medical problem related either to specific drug-related harm, e.g., intravenous users at risk of abscesses, endocarditis, etc., or related to lifestyle, such as malnutrition or tuberculosis. An assessment of mental state is important and this should be monitored during detoxification. Patients may present, for example, with confusion or lowering of mood with suicidal ideation. These symptoms usually do not require anything beyond symptomatic relief and resolve as withdrawal progresses; however, the appropriate level of nursing care and support must be assessed.

Other therapies play an important role in detoxification and can minimize the need for medication. Relaxation training has been said to be a useful way to reduce stress particularly in benzodiazepine withdrawal, and complementary therapies such as massage have also been used to reduce discomfort. Controlled studies of their efficacy are awaited. Competent nursing care is also important. The patient's condition should be assessed accurately, and it has been shown that this can in itself reduce withdrawal symptom scores.¹⁰⁵ Reassurance and attention to nutrition and sleeping patterns also play their part. Any medication prescribed will either substitute for the drug that has been withdrawn or treat the symptoms of the withdrawal syndrome. Consideration must be given to the dosage and the length of time of prescribing.

It has been said that the three most common errors in the management of withdrawal syndromes are (1) failure to diagnose, (2) prescription of too much for too long, and (3) failure to use psychological means to abate withdrawal.¹⁰⁶ The physician must have adequate knowledge both of the symptoms, signs, and duration of the common withdrawal syndrome and of their treatment to guard against all of these.

7.3.2 Opiate-Specific Withdrawal Syndrome

DSM-IV-R¹⁰⁰ describes opioid withdrawal following cessation or reduction in heavy and prolonged use of either illicit drugs or prescribed medication. The syndrome described consists of craving for the drug and three or more of the following symptoms: dysphoric mood, nausea or vomiting, lachrymation and rhinorrhea, muscle aches, pupillary dilatation, piloerection, diarrhea, yawning, or insomnia. The signs and symptoms should develop acutely within days of cessation of drug use and be severe enough to impair a patient's functioning. In addition to this, body temperature and blood pressure may be slightly elevated with a variable effect on pulse. As discussed earlier, the onset of a withdrawal syndrome will depend on the quantity of the drug used and the route of administration,¹⁰⁷ as well as the frequency of usage, and the half-life of the drug. Heroin withdrawal normally begins 6 to 8 h after last use, symptoms peak at 2 to 3 days, and have usually resolved within a week. Withdrawal from other opiates is similar but will exhibit different time scales and intensities, e.g., methadone withdrawal may last for several weeks and not commence for 36 to 48 h. Opioid withdrawal can also be precipitated by an antagonist such as naloxone, which will produce a severe withdrawal with peak intensity about 30 min from administration.

The opiate withdrawal syndrome is very rarely life-threatening and has been described as being similar to having influenza. It is, however, experienced as sufficiently unpleasant for it to be avoided

whenever possible by users and for its successful negotiation to be the necessary first step toward abstinence. For this reason it is important that it is properly managed by the clinician.

The essential judgment in a planned detoxification is about its speed. A rapid detoxification will produce more severe withdrawal symptoms than a slower one, but it may be easier to maintain motivation. There are a number of different pharmacological approaches that may be used and tailored to the individual's requirements. A brief review of the use of methadone, alpha-2-agonists, and buprenorphine in detoxification is given.

7.3.2.1 Detoxification Using Methadone

A wide variety of different regimens has been used and there is some lack of clarity between those that are long-term slow reductions and merge with methadone maintenance therapy (MMT) and those that are short term and aimed at immediate abstinence. In clinical practice patients who are on methadone maintenance treatment will usually have their methadone dose reduced gradually, commonly at a rate of 5 mg every 2 weeks to a daily dose of 20 to 30 mg. Reductions then occur in smaller increments to zero. In the U.K. there is no recommended time for this process of reduction to continue. In the U.S. the FDA regulations permit extended opioid detoxification for up to 6 months.

Various time scales for withdrawal have been studied.¹⁰⁸ It is important to inform patients about what to expect during detoxification as almost everyone undergoing methadone reduction will experience withdrawal symptoms. These have been shown to be a major factor in precipitating relapse. However, data from the literature are hardly comparable; programs vary widely with regard to duration,¹⁰⁸ design,¹⁰⁹ and treatment objectives, impairing the application of meta-analysis. A recent review by Amato¹¹⁰ confirmed that slow tapering with temporary substitution of long acting opioids (methadone), accompanied by medical supervision and ancillary medications can reduce withdrawal severity. Nevertheless the majority of patients relapsed to heroin use.

Negotiation between prescriber and patient about rates of reduction together with the understanding that extra psychological support will be available during detoxification are also important. The setting for detoxification should be given consideration.¹¹¹ Opioid users are likely to live in environments with other drug users, which makes abstinence difficult to achieve. It may be appropriate to consider the initial reductions of methadone as an outpatient and then admit the patient to finally achieve a drug-free state.

Methadone reduction regimens have been de rigueur in many clinical settings but in practice it is often difficult to achieve abstinence by this method, with patients often becoming "stuck" when low doses of methadone (15 mg/day) are reached. Indeed it has been said that "most methadone treatment is maintenance treatment because most patients fail detoxification."¹¹² Although it is a common clinical problem, the cause is not clear. It may be that the withdrawal symptoms become intolerable. Another explanation is that the drug user wants to seek a drug effect which is lost at lower dosages. Current practice suggests that methadone reduction should be attempted in combination with other psychological interventions and other pharmacological agents (buprenorphine).

7.3.2.2 Detoxification Using Buprenorphine

There is an emerging evidence base for the use of buprenorphine (BPN) in detoxification regimens. For detoxification, most comparative randomized trials have been against symptomatic medications (e.g., clonidine, benzodiazepines). The evidence suggests that BPN is more effective in reducing withdrawal severity, increasing detoxification completion rates, and increasing uptake of post-detoxification (e.g., naltrexone maintenance) treatment. There is less research directly comparing BPN and methadone reductions, although the evidence suggests there is less "rebound" withdrawal (symptoms after stopping medication) following short courses of BPN compared to methadone.

Table 7.3.1 Selecting Medications: Advantages and Disadvantages of BPN Compared to Methadone

Advantages	Disadvantages
Greater blockade of heroin use	Blockade not desired by some patients
Smoothen opiate effect and less sedating than methadone	Some patients do better with sedating effects of high-dose methadone
Safer in overdose than methadone	Tablets easily abused if not supervised
	Safety in pregnancy not yet established
Milder withdrawal than methadone	Mild withdrawal may make it too easy to “jump off”
3 or 4 times a week supervised dosing possible for most clients (~66%)	Supervised dispensing more time-consuming
Some clients prefer BPN	Some clients prefer methadone

BPN can be used in brief detoxification regimens over 1 to 2 weeks in inpatient or outpatient settings to assist individuals detoxifying from heroin; or in more gradual outpatient reduction regimens lasting several weeks to months. Longer-term reduction regimens appear to be associated with more “rebound withdrawal,” but do allow a greater opportunity for the patient to “stabilize” while in treatment. As in any detoxification program, a key aspect is to facilitate patients continuing in ongoing treatment for their dependence. This may entail naltrexone treatment, counseling, or rehabilitation programs for those aiming to achieve abstinence, or continuing in maintenance BPN treatment for those unable to immediately achieve long-term abstinence.

The milder withdrawal syndrome associated with BPN compared with methadone suggests that transfer to BPN may be one option for stable patients who are ready to cease maintenance substitution treatment, but are experiencing difficulties withdrawing off methadone.¹¹³ There have been a number of fixed-dose and flexible-dose Phase III randomized trials comparing BPN to methadone maintenance treatment, recently reviewed in a systematic Cochrane review.¹¹⁴ Fixed dose studies suggest comparable efficacy when used in equivalent doses (low dose, 20 to 35 mg, methadone is broadly equivalent to low dose, 2 to 4 mg, BPN), although to date there have been no trials comparing “gold standard” high dose (e.g., 80 to 120 mg) methadone to high dose (e.g., 16 to 32 mg) BPN treatment. Flexible dosing studies have identified greater early treatment drop-out among BPN patients, which may reflect the slow BPN induction regimens used in these trials.

The increased range of opioid pharmacotherapies potentially allows for better tailoring of medications to suit the patient’s treatment objectives. While research suggests comparable efficacy between the two medications, it is yet to provide a clear indication of which individuals will benefit most from maintenance treatment with either BPN or methadone. Without a clear evidence base, clients and clinicians must consider a range of factors when selecting a pharmacotherapy, including a patient’s past history of response to a medication, individual variation in pharmacokinetics (e.g., rapid methadone metabolizers), adverse events, logistics of participating in treatment (such as costs, accessibility of services), and patient (and clinician) expectancy. Particular issues in selecting BPN and methadone are shown in Table 7.3.1.

Substitution treatment (such as methadone) has historically been confined to specialist clinic-based programs. Recent decades have seen the expansion of substitution maintenance and detoxification treatment into primary care (general practice and community pharmacy) settings in many countries in order to “normalize” addiction treatment, reduce treatment costs, and increase the accessibility of services. This trend has extended to the U.S., where trained and accredited physicians can deliver BPN treatment outside of clinic settings (“office based prescribing”). Increasingly, the role of specialist services is to target patients with more complex treatment needs (e.g., polydrug dependence, severe social dysfunction, or medical or psychiatric comorbidity).

A number of studies have examined the acceptability and effectiveness of BPN in the treatment of opiate dependence. It has been shown that BPN treatment is as effective as methadone in the detoxification of heroin users.¹¹⁵ BPN has been shown to attenuate self-administration of illicit opiates in opiate-dependent individuals. The study used a daily dose of 8 mg of subcutaneous BPN and recorded a 69 to 98% suppression of heroin self-administration, which compares favorably to

the opiate antagonist naltrexone.¹¹⁶ Treatment with opiate antagonists (e.g., naltrexone) can be commenced as soon as 24 h after the cessation of BPN without precipitating severe opiate withdrawal; in comparison, naltrexone usually precipitates severe withdrawal if initiated within days of heroin or methadone use.

There are a number of different pharmacological options available for the treatment of opiate withdrawal and it is important to tailor detoxification to suit each individual. As Seivewright and Greenwood²⁴ point out, a 17-year-old who has been using heroin for 6 months with few social problems will require treatment different from a 35-year-old injector of heroin with a long history of dependence and failed previous detoxifications. The first patient may do best being detoxified using lofexidine; the second may need a long-term methadone reduction program. There is a need for further research to establish precisely which group of patients is likely to do best with which treatment.

7.3.2.3 Detoxification Using Adrenergic Agonists

A subgroup of the adrenergic agonists are the alpha-2 agonists clonidine and lofexidine, which are being increasingly used in opiate detoxification. Chronic administration of opiate drugs results in tolerance to the effects mediated by opiate receptors such as euphoria, and tolerance to the effects of opiates on the automatic nervous system, which is mediated by noradrenergic pathways. The locus coeruleus in the dorsal pons is the origin of much of the central nervous system noradrenergic activity. It is associated with opiate and presynaptic alpha-2-noradrenergic receptors, which are inhibiting.

Chronic opiate intake leads to tolerance and to stimulation of the opiate receptors. Abrupt withdrawal leads to an escape from this inhibition and a rebound rapid firing of the neurons. A “noradrenergic storm” results and is responsible for many of the opiate withdrawal symptoms.¹¹⁷ Clonidine and lofexidine act as presynaptic alpha-2-adrenergic agonists, which inhibit this and therefore are able to attenuate symptoms. However, those experiencing the most severe withdrawal symptoms are not well controlled by clonidine and the symptoms of arthralgia, myalgia, anergia, and insomnia were not alleviated. Its use has also been limited because of its potentially serious side effects, which include hypotension, sedation, and psychiatric symptoms in those who are vulnerable.

Lofexidine is a newer alpha-2-adrenergic agonist (licensed in the U.K. since 1992), which appears not to have the same problems with side effects and which has gained in popularity as a non-opiate for use in detoxification in a variety of settings. Lofexidine when used to withdraw patients from methadone demonstrated good completion rates, and there were no reports of significant lowering of blood pressure or sedation. However, residual withdrawal symptoms with insomnia, lethargy, and bone pain mentioned and were observed in users stabilized on relatively low doses of methadone.

Bearn et al.¹¹⁸ conducted the first randomized double-blind study comparing methadone and lofexidine detoxification in 86 polydrug-abusing opioid addicts. The lofexidine group experienced more severe symptoms from day 3 to day 7 and by day 20 both groups showed a similar progressive decline in symptoms. The two treatments had similar effects on blood pressure and treatment completion.

7.3.2.4 Naltrexone-Assisted Detoxification

In an attempt to reduce the duration of the opiate withdrawal syndrome, particularly from long-acting opioids such as methadone, combinations of compounds have been used. A rapid process using scopolamine with naltrexone and naloxone has been reported.¹¹⁹

More recently interest has been shown in very rapid (<48 h) opiate detoxification, using opiate antagonists and general anesthesia. However, this method is expensive and adds a risk of death to a nonfatal condition. Reports of delirium from rapid opioid detoxification have also emerged.¹²⁰

The addition of other medications to lofexidine in detoxification (such as hypnotics, muscle relaxants, and antidiarrheal medication) may need to be considered on an individual basis. Other

short-acting opioids such as dihydrocodeine have been used in detoxification regimens although there is little evidence for their efficacy. One regimen employed involves a crossover period from low dose (30 mg or less) methadone to the equivalent dose of dihydrocodeine over 7 to 10 days and then a reduction of dihydrocodeine over the following 7 days.¹²²

7.3.3 Stimulant-Specific Withdrawal Syndrome

Withdrawal symptoms of these drugs, manifest in broad terms as the inverse of the stimulant effects, can be explained by the neurochemical changes that they induce. The existence of a withdrawal syndrome was for some time controversial because of the lack of physical withdrawal symptoms and signs. During the 1980s, the use of cocaine in the form of crack increased dramatically in North America and this has led to an increase in clinical and research evidence about its dependence-forming properties and withdrawal syndrome. DSM-IV-R¹⁰⁰ defines both amphetamine and cocaine withdrawal in the same way.

The symptoms are characterized by a constellation of signs and symptoms that appear within a few hours to several days after either cessation or reduction in heavy or prolonged use of the drugs. The symptoms must not be due to another medical or mental disorder and must cause impairment of functioning. It is described as consisting of dysphoric mood and two or more of the following: fatigue, vivid and unpleasant dreams, insomnia or hypersomnia, increased appetite, and either psychomotor retardation or agitation. Drug craving and anhedonia may also be present. Cocaine withdrawal has been reported to reach its peak in 2 to 4 days, with symptoms such as lowering of mood, fatigue, and general malaise lasting for several weeks. Amphetamine withdrawal is also reported to peak within 2 to 4 days with the most characteristic symptoms being lowering of mood and associated suicidal ideation.

Most of the recent studies looking at stimulant withdrawal have investigated cocaine. However, given the different pharmacokinetics of amphetamine and cocaine it would be reasonable to expect quite different time courses for the appearance, peak, and duration of the respective withdrawal syndromes. The half-life of cocaine is approximately 1 h, with the onset of action between 8 s and 30 min depending on the route of administration. The duration of effect is reported to be between 5 and 90 min.¹²³ Conversely, the half-life of amphetamine is about 10 to 15 h, with its onset of action and duration of effect two to eight times as long as cocaine. This would lead to the expectation that amphetamine withdrawal would have a slower onset on action, last longer, and be less intense than cocaine withdrawal. Further controlled studies in humans need to be done to confirm this. Our current concepts of amphetamine withdrawal are based largely on clinical impressions and animal studies.

The main physical and psychological effects of cocaine and crack have been recently reviewed. Users feel stronger, more alert and energetic, confident and physically strong. Common physical effects include dry mouth, sweating, loss of appetite, and increased heart rate. When snorted, cocaine produces a slow wave of euphoria followed by a plateau and a "comedown." Smoked as crack, the drug has a much more intense and immediate effect. Excessive doses can cause severe medical problems including death from pulmonary edema, heart failure, and myocardial infarction.

Substantial numbers of people who are cocaine dependent will not report or have clinically evident withdrawal symptoms even after cessation of heavy and prolonged use.¹²⁴ This, combined with clinical observations, suggests that stimulant withdrawal is associated with considerable heterogeneity. It has been said to depend on dose of drug, pattern of use, duration of history, and pre-withdrawal psychopathology.¹²⁵ Patterns of use may vary from daily use to a common pattern of using for several days at a time followed by days of abstinence. This will have an effect on the appearance of withdrawal symptoms and their severity.

Stimulants do not produce dangerous physical withdrawal syndromes, and because of this there is no advantage to a gradual withdrawal of the drug. Patients should be advised to discontinue the drug abruptly. Advice and information should be given about the likely effects of cessation and consideration given to the setting for detoxification. Those patients who present with mild symptoms

that last a matter of hours or days usually are not a management problem. Symptomatic treatment for agitation or anxiety with a drug of low abuse potential such as thioridazine may be necessary.

More severe withdrawal symptoms may require admission. Close observation will be necessary for those expressing suicidal ideas. Symptomatic relief for other symptoms such as anxiety and insomnia may be required. Having achieved abstinence, the next phase is to identify psycho-social problems and initiate interventions designed to maintain a drug-free state and deal with drug craving. A number of different pharmacological treatments have been used mainly in cocaine dependence to treat the dysphoric symptoms associated with withdrawal and to attempt to reduce craving. These are reviewed in Chapter 7.4.

The small numbers of studies, the absence of physical withdrawal symptoms, and the variation in patterns of drug use make stimulant withdrawal more difficult to characterize than with other groups of drugs. Cocaine has been studied because of the “crack” epidemic of the 1980s, and has led to an increase in our understanding of both the symptoms and the underlying neurochemistry of withdrawal. Numerous different agents have been used to attempt to treat the drug craving and mood disorders associated with withdrawal, all with limited success. Less is published about amphetamine withdrawal and details of ecstasy withdrawal are scarce. Any comparisons with cocaine should not forget the differences in the drugs’ properties and pharmacokinetics.

7.3.4 Hypnotic and Sedative Withdrawal Syndrome

In practice it is the benzodiazepines that dominate the market for both hypnotics and anxiolytics. Barbiturates such as secobarbital, pentobarbital, and amobarbital are under the same federal controls as morphine in the U.S. and in the U.K., and they are rarely prescribed.

DSM-IV-R¹⁰⁰ criteria for sedative, hypnotic, or anxiolytic withdrawal require two or more of the following to be present:

1. Autonomic hyperactivity (e.g., sweating or pulse rate greater than 100)
2. Increased hand tremor
3. Insomnia
4. Nausea or vomiting
5. Transient visual, tactile, or auditory hallucinations or illusions
6. Psychomotor agitation
7. Anxiety
8. Grand mal seizures

Physicians can then specify if perceptual disturbances are present. As in other classes of drug, the withdrawal symptoms are the opposite of the drug effects and are explained by the underlying changes in neurophysiology largely via the gamma aminobutyric acid (GABA) system. GABA is the most widely distributed inhibitory neurotransmitter in the central nervous system. Close to its receptors are specific receptors for the benzodiazepines and the barbiturates. When these are activated, the action of the GABA system is potentiated causing further inhibition. With continued drug use, the number of GABA receptors falls due to downregulation.

When GABA binds with its receptor it causes hyperpolarization of the neuron as the chloride channel is activated and hyperpolarization is reversed by increased entry of calcium to the cell. If drug use ceases, the increased intraneuronal calcium produces a state of hyperexcitability. The reduction in the number of GABA receptors has the effect of reducing the overall effect of the main inhibiting system resulting in the symptoms previously listed.

Benzodiazepines dependence is not a single entity and varying different classifications have been proposed. Perhaps the most useful division within the context of drug abuse is the division between high-dose and normal-dose dependence. Non-abusers who are dose dependent take their benzodiazepines within the recommended therapeutic range and remain on this regimen long term. These people may want to do without their medication but feel unable to because of the withdrawal

symptoms experienced upon cessation of their medication. In high-dose misuse, up to ten times the normal recommended dosage may be consumed on a regular basis.

Benzodiazepine withdrawal can be classified in several ways. A division between minor and major withdrawal is sometimes used and this emphasizes the severity of the symptoms. Symptoms associated with low-dose withdrawal are nausea, vomiting, tremor, incoordination, restlessness, blurred vision, sweating, and anorexia. Depersonalization, heightened perceptions, and illusions are also described. In a review of recent studies, Alexander and Perry¹²⁶ concluded that symptoms occurred in 50% of those withdrawn from therapeutic doses of benzodiazepines with an average use of 3 years and most symptoms were mild to moderate.

Discontinuing high doses of benzodiazepines can produce all the minor symptoms discussed, but patients are also at risk of seizures, psychosis, and depression. Early studies indicate a high risk of severe withdrawal when high doses are discontinued. The incidence and the severity of withdrawal symptoms can be predicted to some extent by the dose and duration of use. The time course is influenced by the half-life of the drug. Those with a short action may begin to produce mild withdrawal symptoms within 1 to 5 days of ceasing use and usually disappear over 2 to 4 weeks. Drugs with a longer half-life may not produce withdrawal symptoms for 1 to 2 weeks after use ceases and they are likely to be less severe, but more prolonged.

7.3.4.1 Management of Withdrawal

Sudden withdrawal of benzodiazepines is not advised. For an uncomplicated low-dose withdrawal, a gradual tapering of the drug is recommended. If patients are on a short-acting drug, then they may be switched to a longer-acting drug with the rationale that less severe withdrawal symptoms occur with long-acting drugs. Diazepam has been the most widely studied, and conversion data from common benzodiazepines are available. Once stabilized this can then be reduced. A number of different schemes are available. The tapering dose can be calculated by dividing the total dose by 5 and reducing by this amount weekly. Most patients can be reduced to zero in 4 to 8 weeks. Slower withdrawal may be necessary toward the end of the reduction and consideration should be given to admission if withdrawal symptoms become very intense.

In high-dose withdrawal, the picture is often complicated by other illicit drug or alcohol use. A conversion to diazepam may be difficult because of problems in establishing dosage and frequency of use. Concomitant use of alcohol is particularly common. Most clinicians would withdraw the alcohol after establishing the patient on a stable dose of a long-acting benzodiazepine. Benzodiazepines are also commonly taken by opiate users to boost the opioid effect.¹²⁷ In North America it has been found that alprazolam was replacing diazepam as the drug of choice in this population. For those patients where an accurate and reliable history of drug intake is not available, then admission is indicated for tolerance testing performed to assess tolerance and severity of withdrawal before planning a detoxification regimen.

7.4 REPLACEMENT PRESCRIBING

Kim Wolff, Ph.D.

King's College London, Institute of Psychiatry, National Addiction Centre, London, U.K.

7.4.1 Opioid-Specific Prescribing

Antagonists have zero efficacy and as such are very effective blockers of agonists. Their main limitations are that they can precipitate withdrawal in physically dependent drug users, and because

they do not provide any reinforcement, there is little incentive for those dependent on illicit drugs to be compliant. Naltrexone is a long-acting, orally effective competitive antagonist at opioid receptors. It displaces any agonist present at the receptors and blocks the effects of any opioid subsequently administered. Naltrexone is predominantly metabolized by the liver and its major metabolite, 6-beta-naltrexol, is also an active opioid antagonist. The opiate-blocking effects of naltrexone last between 48 and 72 h. Naltrexone has not been shown to produce tolerance and therefore does not lead to physical dependence.¹²⁸

Oral administration of naltrexone to an opioid-dependent individual results in the immediate appearance of a severe opioid withdrawal syndrome. It is therefore necessary to be completely detoxified from opioid prior to commencing naltrexone treatment. It is necessary to discontinue short-acting opioids such as heroin for approximately 5 to 7 days prior to commencing naltrexone. Longer-acting opioids such as methadone need to be discontinued for approximately 10 to 14 days before naltrexone can be successfully commenced. In the event of naltrexone being given prior to the end of detoxification, it is likely that withdrawal symptoms will appear. This, in turn, makes it much less likely that the individual will agree to taking naltrexone at any point subsequently despite reassurance from the prescribing doctor.

Successful naltrexone treatment depends on careful selection of individuals and understanding that naltrexone treatment is only a small part of the relapse prevention package. Psychological treatment looking at issues, such as craving, drug-refusal skills, and making appropriate lifestyle changes, should be administered at the same time as naltrexone. A positive outcome is more likely in those who are well supported by friends or family members and those who had good pre-morbid adjustment in terms of education, employment, and social class. Naltrexone treatment is contraindicated in people with acute hepatitis or liver failure. It is necessary to check liver function tests both prior to and during naltrexone treatment.

Individuals who are due to start on naltrexone should be informed of the possible side effects, which include gastrointestinal disturbances such as nausea, vomiting, abdominal pains, and diarrhea. They should also be warned of the potential dangers of trying to overcome the naltrexone blockade by taking large doses of opioids. This can lead to respiratory depression and death. It is also important for those prescribed naltrexone to understand that they will be unable to use opioid analgesics for mild pain. They should be advised about non-opiate alternatives. If opioid analgesia is required, this should be administered in a hospital setting under the supervision of trained staff. Naltrexone should be discontinued 72 h prior to elective surgery and reinstated once the surgical procedure has been performed.¹²⁹

Prior to prescribing naltrexone for the first time, it is necessary to confirm that an individual is abstinent from opioids. This can be done by means of urine toxicology or by performing a "naloxone challenge." This involves the intravenous or intramuscular administration of the short-acting opiate antagonist naloxone. If opioid withdrawal symptoms are not precipitated, then it is appropriate to commence naltrexone approximately 1 h later. If opioid withdrawal symptoms are present, then naltrexone treatment should be deferred until the naloxone challenge has been repeated without the appearance of withdrawal symptoms.

Naltrexone (25 mg) should be given on the first day, followed by daily dosing of 50 mg thereafter. A dose of 50 mg naltrexone blocks the effects of 25 mg of heroin for up to 48 h, 150 mg of naltrexone blocks the effects for 72 h. To supervise the swallowing of naltrexone tablets and improve compliance, it is possible to prescribe naltrexone three times per week (i.e., 100 mg on Monday and Wednesday, 150 mg on Friday). Due to the variable nature of opioid dependence, the length of time that people are required to take naltrexone varies between individuals. Naltrexone prescribing should continue, in the absence of complications or contraindications, until the individual is confident that it is possible to resist the temptation to return to dependent use of opioid drugs. This time span may be only a few weeks but can be as long as a few years in some cases.

In summary, naltrexone is a competitive opioid antagonist that displaces opioid agonists from the opioid receptors and blocks the effects of opioid agonists subsequently administered. It is a

useful adjunct to psychological relapse prevention methods in well-motivated individuals receiving treatment for opioid dependence.

7.4.2 Stimulant-Specific Prescribing

A useful pharmacotherapy for stimulant (cocaine and amphetamine) dependence remains elusive. As a rule, symptoms of stimulant withdrawal are not medically dangerous. Detoxification from these substances requires no treatment other than abstinence. However, many users find the symptoms of cocaine withdrawal intensely dysphoric and immediately relapse and reuse cocaine in order to fend off the symptoms. The addictive nature of stimulants, particularly crack, the freebase form of cocaine, is, in part, the result of their effects on the neurochemistry of the brain. Stimulant drugs act directly on the so-called brain reward pathways.

One of cocaine's primary effects in the brain is to block the presynaptic reuptake of dopamine, norepinephrine, and serotonin, whereas amphetamine and methamphetamine increase the release of these neurotransmitters. Chronic use of cocaine results in dopamine depletion through the increased activity of catechol-*o*-methyl transferase, and supersensitivity of the dopamine, norepinephrine, and serotonin receptors, while both catecholamine and indolamine transmitters are depleted. Chronic use of cocaine seems to compromise the body's ability to regenerate these neurotransmitters causing withdrawal symptoms when the user stops. Withdrawal symptoms manifest as the inverse of the stimulant's effects. Acute tolerance, rebound depression (or the crash), and craving for stimulant drugs have been specifically attributed to dopamine depletion and receptor supersensitivity. Neurochemical changes also explain the withdrawal syndrome, which includes lethargy, depression, oversleeping, overeating, and craving for more cocaine. Extinguishing drug craving is one of the most difficult aspects of treating stimulant dependence.

7.4.2.1 *Neurochemical Approach: Dopaminergic Agents and Selective Serotonin-Reuptake Inhibitors*

The involvement of multiple neurotransmitter systems during stimulant use have complicated the search for pharmacological agents to address dependence. A variety of data suggest that dopamine is an important mediator for stimulant self-administration. As a result, drugs that modify dopaminergic neurotransmission are of interest as potential treatments for stimulant use. Both agonists and antagonists have been studied in this regard, agonists because they mimic the effects and act as a stimulant substitute, theoretically reducing or eliminating drug intake and antagonists because they might reduce the reinforcing properties of stimulants and facilitate abstinence. However, a review of evidence shows little or no support for the clinical use of dopamine agonists, mazindol, phenytoin, nimodine, amantadine, bromocriptine, carbamazepine, bupropion (Zyban), and chlor-diazepoxide in the treatment of cocaine dependence.¹³⁰

Dopamine Agonists

Bromocriptine (Parlodel) is an agonist at the D₂ receptor. It acts by stimulating dopamine receptors in the brain and was thought to reduce some symptoms of cocaine withdrawal, have anticraving effects, and was effective as an antidepressant, alleviating the low mood that accompanies the cocaine crash. However, other more recent studies using a controlled approach have not supported the general usefulness of this drug.¹³¹

Amantadine (Symmetrel) is an indirect dopamine agonist. Open-label pilot studies in primary cocaine users and methadone-maintained cocaine users have indicated that amantadine might reduce cravings for cocaine.¹³² The lack of efficacy of amantadine for the reduction of craving or cocaine recently reported by Hendelson¹³³ is consistent with those of other placebo-controlled clinical trials in methadone-maintained patients.¹³⁴ Amantadine, while well tolerated, is not particularly efficacious for the reduction of cocaine use or cocaine craving.¹³⁵

Methylphenidate (Ritalin) may reduce cocaine cravings in patients with attention-deficit disorder, possibly because of its ability to stimulate the central nervous system. However, the abuse potential of this drug severely limits its, and other similar drugs', usefulness as a treatment for cocaine misuse.

Dopamine Antagonists

Flupenthixol, a dopamine antagonist, has also shown promise in treating cocaine withdrawal; however, Spiperone has not reduced the effects of cocaine in mice, rats, or dogs.¹³⁶

Dopamine Partial Agonists

Aminoergolines (Terguride and SD208911), medications that act as partial agonists at the dopamine receptor, may be candidates for normalizing dopamine transmission. The efficacy of the partial agonist depends on the level of occupancy of a given receptor by full agonists, such as dopamine. Consequently, partial agonists function as antagonists during pharmacological stimulation due to stimulant use when transmitter activity is high. By occupying dopamine receptors and exerting low intrinsic activity, partial agonists might represent a novel antipsychotic agent. However, human self-administration studies have yet to be performed.

Buprenorphine: Recent evidence suggests that the dopamine reward system of the brain is also stimulated by μ -opiate agonists. Over the past 5 years there has been significant interest in buprenorphine, a partial agonist, as a potential treatment agent for cocaine abuse. Preclinical primate work suggests that buprenorphine might modulate dopaminergic systems to the degree of altering the reinforcing properties of cocaine. However, there may be inherent problems in prescribing a medication with opiate agonist properties to opiate-naïve individuals in an effort to treat cocaine dependence, particularly in a population with a known vulnerability for addiction to substances with a demonstrated abuse liability.¹³⁷

Selective Serotonin-Reuptake Inhibitors

In addition to the blockade of dopamine reuptake, cocaine is thought to produce an increase in serotonergic tone. Therefore, it was felt that drugs that modify serotonergic neurotransmission may also alter the behavioral effects of cocaine and be potentially useful as therapies for cocaine users. However, fluoxetine (Prozac) and lofepramine are important only if underlying depression is confirmed. Selective serotonin-reuptake inhibitors (SSRIs) should be used with caution if cocaine use persists because of the rare occurrence of the "serotonergic syndrome," which is characterized by changes in autonomic neuromotor and cognitive-behavioral function triggered by increased serotonergic stimulation.¹³⁸

7.4.2.2 Clinical Approach, Tricyclic Antidepressants, and Antisensitizing Agents

The other main approach for the treatment of stimulant dependence is clinical because the clinical syndrome that evolves after the discontinuation of cocaine or amphetamine resembles a depressive disorder. And it is widely held that antidepressant medications may have clinical utility in alleviating drug craving and self-administration. Neurochemical and clinical rationales are not mutually exclusive, and an antidepressant agent that reduces the clinical phenomena observed after cessation of cocaine might also have significant dopaminergic activity that would be consistent with a neurochemical approach to treating cocaine use.

Tricyclic Antidepressants

Since chronic tricyclic antidepressant treatment has been shown to downregulate adrenergic and dopaminergic receptor sensitivities, it has been suggested that antidepressant agents could reverse the neuroreceptor adaptations to cocaine abuse.

Desipramine (Pertofran) has been studied as an adjunct to reducing cocaine use in patients because of its high degree of selective noradrenergic activity and inhibition of the norepinephrine transporter.

Imipramine (Tofranil): Tricyclics generally exert only modest anticraving and antieuphoriant effects, which may translate into reduced cocaine use and this is certainly the case with imipramine. Carroll¹³⁹ found that the antidepressant, anti-self-medication effect of imipramine was better in depressed users. Intravenous and freebase crack users showed poor outcome with imipramine. It seems likely that tricyclics such as imipramine are most effective in specific subgroups, e.g., nasal users who are exposed to less cocaine, or patients with comorbid depression, where depression plays a role in initiating or perpetuating cocaine use.

7.4.3 New Approaches

Immunopharmacotherapy is a new strategy to treat cocaine use. It has been developed in rodents by Carrera et al.,¹⁴⁰ who proposed generating an active immunization to cocaine to block the actions of the drug. Active immunization against cocaine is accomplished by linking stable cocaine-like conjugates with a foreign carrier protein to stimulate the immune system to produce antibodies that subsequently recognize and bind the drug preventing it from entering the central nervous system and thereby exerting psychoactive effects. However, there are many problems to be addressed before immunization is to be effective in preventing or treating cocaine addiction in humans.

The National Institute on Drug Abuse (NIDA) is currently looking at ways to neutralize the drug in the bloodstream and reduce the amount available for brain uptake. Scientists are trying to develop catalytic antibodies, synthetic molecules that will target and break down cocaine molecules more quickly than the body's natural enzyme systems and, therefore, limit the amount of drug crossing the blood–brain barrier. The literature reveals no pharmacological agent that has been demonstrated in large double-blind studies to be significantly better than placebo for stimulant dependence in men and women. While several medications appear promising and will require more extensive investigation, many of the positive clinical reports are anecdotal and uncontrolled. At present, it remains difficult to justify routine clinical use of a single pharmacological agent.

7.5 MANAGEMENT OF COMORBIDITY

Duncan Raistrick, M.B.B.S.

The Leeds Addiction Unit, Leeds, U.K.

7.5.1 Understanding Comorbidity

Comorbidity is defined as the coexistence of two or more psychiatric or psychological conditions; for the purposes of this section, one of these conditions will be substance misuse or substance dependence. It is usual to take ICD-10 or the *American Diagnostic and Statistical Manual*, now in version DSM-IV-R,¹⁰⁰ as the descriptive classification of these conditions. Practitioners are usually concerned with current comorbidity, but from the point of view of understanding etiology and deciding upon rational treatment approaches it may be more useful to think in the longer term. Estimates of comorbidity will be influenced by methodological factors including the diagnostic criteria, time frame, and the population sample: there will be marked differences, for example, between general population and treatment population samples, or even between groups assigned to different treatment programs. In spite of these difficulties, some general conclusions are evident.

Wittchen et al.¹⁴¹ looked at key international studies of comorbidity in community population samples and concluded that there were strong similarities between different countries; summarizing

two large studies from the U.S., they state: (1) over half of those individuals who have a substance misuse problem have also experienced other mental disorders within their lifetime, (2) dependence on, rather than misuse of, alcohol or other drugs is more likely to be associated with a mental disorder, (3) major depression, anxiety disorders, phobias, mania, schizophrenia, and conduct disorder in adolescence or adult antisocial behavior are all strongly associated with substance dependence, and (4) social phobia and adolescent conduct disorder are also associated with alcohol or drug misuse.

The National Comorbidity Survey of the general adult population in the U.S. studied lifetime and 12-month comorbidity in more than 8000 subjects: the lifetime prevalence for any substance misuse or dependence disorder was 26.6% and 12-month prevalence was 11.3%, with males having approximately twice the rates of women.¹⁴² These data imply considerable variation and possibly substitution of mental disorders, one with another, over time. The stability of substance-related comorbidity is of importance in determining treatment regimens. Clinicians generally underestimate the presence of psychiatric and psychological disorders when assessing patients with substance misuse problems. Clinicians expect high levels of morbidity and often assume that symptoms are due to withdrawal, transient physical problems, or dependence itself. To determine the true prevalence of comorbidity in a treatment population, Driessen et al.¹⁴³ studied 100 inpatients' post-alcohol detoxification: they found 3% to have schizophrenia or schizoaffective disorders, 13% affective disorders, 22% phobic disorders, and 2% general anxiety. Alcohol dependence was judged to be secondary to the psychiatric condition in 60% of patients with schizophrenia, 48% with depression, and 72% with phobic disorder. This does not necessarily mean that a psychiatric condition that antedates substance misuse will persist beyond detoxification, or that there is any causal relationship.

It is important for the clinician to know what is driving an individual's substance use. Comorbidity does not imply cause and effect, but is one of several possibilities:

- Substance use and psychiatric disorder may coexist by chance.
- Substance use may cause psychiatric disorder.
- Psychiatric disorder may cause substance use.
- A third factor may mediate both substance use and psychiatric disorder.

Where a psychiatric disorder is seen to be of primary importance and driving the substance use, the psychiatric disorder should be the focus of treatment. However, a psychiatric disorder that initiated substance misuse or precipitated a relapse may be superseded by dependence driving the maintenance of substance use.

7.5.2 Making Prescribing Decisions

As a matter of general principle there are several reasons doctors should be reserved when prescribing for people who misuse alcohol or other drugs: for those who also have a mental health problem there is a risk that prescribing sends out a message that taking drugs, prescribed or otherwise, is an appropriate way to deal with psychological distress. When undertaking a mental state examination, the doctor tries to balance benefits of pharmacotherapy against risk; risk is a function not only of the medication but also the treatment setting. In assessing risk, it is the ephemeral nature of psychological distress coexisting with substance misuse that is perhaps the most compelling reason to wait until a patient is drug free or stable before prescribing, and also a reason to consider hospital admission solely for the purpose of establishing a psychiatric diagnosis.

With a focus on alcohol, Allan¹⁴⁴ has recommended that patients presenting with anxiety and alcohol dependence should first be detoxified and reassessed after 6 weeks when only an expected 10% will be found to have persistent symptoms amounting to an anxiety state. The persistent anxiety can then be treated using conventional pharmacological or behavioral methods. She points out that patients may resist such an approach, preferring to deal with their psychological distress

before tackling their substance use. People who are dependent on alcohol or other drugs usually succumb to a number of financial, family, health, and relationship problems, and it is not surprising that many will complain of depression; again it is not surprising that 80% or more will recover within a few weeks of abstinence without recourse to antidepressant treatment.

While abstinence may enforce an acceptance of problems accumulated while drinking or taking other drugs and this might be anticipated to increase depression, abstinence is also an opportunity to build self-efficacy and self-esteem, both powerful psychological antidepressants. Pharmacological antidepressants should be avoided unless there is unequivocal evidence of a biological depression of mood. The key point is that diagnoses of mental illness and substance use comorbidity made in haste will often evaporate. Nonetheless, it may be that the severity of symptoms is so severe when a patient presents as to indicate immediate symptomatic prescribing without the benefit of a diagnosis. Equally, it may be that a provisional diagnosis, for example, alcoholic delirium or Wernicke encephalopathy, demands urgent treatment.

The general principle to observe and “wait and see” can be a difficult course to follow, and in addition to cases of obvious florid psychosis, there are times when urgent action (usually not pharmacotherapy) is required. For example, suicidal ideation is a common emergency for doctors specializing in addiction. Alcohol and other drugs are commonly found on toxicological screening of subjects who have committed suicide. Depressant drugs in particular are likely to impair judgment and, therefore, increase both the risk of any suicide attempt, but especially suicides involving violence or impulse, such as driving into a bridge or jumping in front of a train.

Murphy¹⁴⁵ has identified seven risk factors for suicide in “alcoholics”:

- Depression
- Suicidal thoughts
- Poor social support
- Physical illness
- Unemployment
- Living alone
- Recent interpersonal loss

The risks accumulate over a number of years, suggesting that there is scope for preventive social and health care. In short, people who misuse alcohol or other drugs are at increased risk of committing suicide: pharmacological treatment risks providing a means of suicide and active, social therapy is more likely to be effective. Other psychiatric conditions may be less urgent than a suicide threat, but nonetheless complex in terms of reaching prescribing decisions.

Insomnia, which may result from psychological distress and may be a symptom of recreational drug use or may be part of a withdrawal syndrome, is ubiquitous and merits special mention. Alcohol and other sedatives increase slow wave sleep and reduce REM and are therefore effective hypnotics. Short-acting hypnotics and alcohol are, in normal amounts, metabolized through the night, causing rebound arousal and awakenings. For people who misuse depressant drugs, including alcohol, the rebound of REM may cause vivid nightmares and sleep disturbance, which persists for months after achieving abstinence. The use of stimulant drugs causes a similar overarousal.

Patients with addiction problems are often reluctant to accept nonpharmacological approaches to insomnia; however, advice to reduce smoking and coffee drinking in the evening and to exercise during the day should at least accompany any prescribing of hypnotics.

In summary, for many people who suffer from psychiatric or psychological disorders, substance use and misuse has utility. It is often the case that traditional medicine has less to offer than the patient's own self-medication regimen and that social rather than pharmacological interventions are really what is needed. It is particularly important for doctors to be clear about the purpose of their prescribing and to monitor its effectiveness. Where substance misuse and psychiatric disorder coexist, the case for not prescribing, even for psychiatric illness, should always be vigorously explored.

7.6 TOXICOLOGIC ISSUES

Kim Wolff, Ph.D.

King's College London, Institute of Psychiatry, National Addiction Centre, London, U.K.

7.6.1 Heat and Drug Stability

The variety of different body matrices that can be analyzed to determine the presence or absence of different psychoactive substances is extensive, ranging from semen to cerumen. There are, however, practical limitations to the extent to which different biological samples can be used, and the mechanism of collection and supervision of samples are critical to the procedure. This chapter focuses on those biological samples that are commonly used for testing within various drug treatment settings, namely, urine, saliva, blood, and hair. Urinalysis is routinely used in hospital-based services, blood in forensic environments, hair analysis for medicolegal cases, and saliva tests have been used in the prison services and outreach units.

Many would advocate that the assessment of psychoactive drug use could reliably be achieved using self-report from the drug user (client). However, there are issues around the method of inquiry — the context, purpose, interviewer characteristics, etc.¹⁴⁶ that may bias self-report. Circumstances where the drug user sees the self-report to the inquirer about drug use as influential on his own continued treatment or possible loss of privileges are particular examples.

The drug being tested for and the period of time that the clinician wishes to consider influence the choice of body fluid. Blood and, to a lesser degree, saliva are likely to give the most accurate measurement of drugs currently active in the system, whereas urine provides a somewhat broader time period, but with less quantitative accuracy. Hair provides a substantially longer time frame.¹⁴⁷

The routine drug testing strategy most widely adopted is to send urine samples to a laboratory for an initial screen to detect psychoactive drugs of interest. Analysis is performed using a semi-automated commercially available immunoassay or thin layer chromatography (TOXILAB) test. Several types of the former test exist and include radioimmunoassay, RIA:Europ/DPC, enzyme-mediated immunoassay test, Syva:EMIT, and fluorescence polarization immunoassay, FPIA. Recently, several rapid detection devices (near patient test, NPT) for drugs of abuse screening have been marketed in the U.K. Such tests offer a more rapid turnaround of results to aid clinical decision making.¹⁴⁸ However, all initial drug screen tests are nonspecific and identify only in a nonquantitative fashion the class of drug present, e.g., opiates, amphetamines, or benzodiazepines, etc.

Ideally, any positive test result should then be confirmed by a second test working on different physicochemical principles to the screening test. Gas and liquid chromatography with mass spectrometric detection are regarded as the “gold standard” and are favored where legally defensible results are required. It cannot be overemphasized that the confirmation of drug screening test results is essential. For amphetamine-specific immunoassays, the confirmation test provides the opportunity to differentiate legitimate medicines. For instance, pseudoephedrine and phentermine give a positive test result (cross-react) with tests for illicit drugs like amphetamine and 3,4-methylenedioxymethamphetamine, MDMA. For opiate drugs, initial immunoassay tests for morphine cross-react with codeine, dihydrocodeine, pholcodeine, 6-monoacetylmorphine (6-MAM), morphine-3-glucuronide, and morphine-6-glucuronide. Consequently, if more than one of these substances is present in a urine sample, the test result will relate to the concentration of the sum of all these opiates and their metabolites. In this way an inaccurate picture of the window-of-detection of opiate drugs in urine may be concluded. The clinical benefit of the confirmation test is that it is able to verify the specific substance(s) present. For example, a confirmation test can detect the presence of 6-MAM, the only specific indicator (metabolite) of heroin use

Table 7.6.1 Checks for Urine Sample Adulteration

Problem	Check to Confirm
Dilution	Creatinine <20 mg/dl (1.77 mmol/L) Specific gravity <1.003
Substitution	Creatinine 5 mg/dl (0.44 mmol/L) Specific gravity 1.001 or 1.020
Concentration	pH values of <4 and >8 are abnormal
Temperature	Values <32°C and >38°C are abnormal
Adulteration (bleach, nitrate)	Sample will not smell like urine Nitrite level >500 g/ml

7.6.2 Analysis Using Other Body Fluids

The advantages of urine sampling for detecting drugs of abuse are the higher drug concentrations; the large volume of urine; the opportunity to concentrate urine samples, which in turn, increases drug concentrations, and thus the possibility of detection; and the fact that urine collection is a non-invasive procedure. Urine testing is the most reliable and interpretable process available to the clinician and is the technique universally supported by laboratories across the country. Urine testing is recommended as essential to help confirm opiate dependence before commencing substitute prescribing with methadone or buprenorphine. Random urine tests are also used to monitor illicit drug use during treatment. Hair testing is more common in occupational health setting and for medicolegal cases where a longer history of drug use is required. Providing the client's hair is of sufficient length (hair grows at a rate of 1 cm/month) and thickness (50 to 100 strands are needed), a drug history covering a 3-month period may be obtained. Cannabis use, however, is very difficult to detect in hair and different rates of drug deposition in the hair strand have been identified for different races, treated (bleached hair), and in blond compared to black-haired people. Blood (and possibly saliva) provides an accurate picture of the immediate situation and is best suited for therapeutic drug monitoring, which has been reported for methadone treatment.

Sample integrity has frequently been an issue with urinalysis and every effort should be made to avoid substitution or adulteration of specimens. Simple observational checks of foaming, color, and temperature are valuable. Collection cups with temperature indicator strips are available for immediate monitoring of specimen temperature. For workplace or pre-employment testing, medicolegal work and sport testing, chain-of-custody procedures, tamper-free collection vesicles, and documentation to accompany each sample are required.

Dilution is a commonly reported problem. The U.K. National External Quality Assessment Scheme (UKNEQAS) for drugs of abuse screening in urine reported that 86% of samples found adulterated had been diluted.¹⁴⁹ As it is possible to drink large volumes of water and lower urine drug concentrations below the positive cutoff, thresholds for tests of urine creatinine and specific gravity have been proposed (Table 7.6.1).

There has been a huge growth in the development of NPT kits. Most are predominantly for urine sample collection and have the advantage of offering rapid results. Such tests include FRONT-LINE (Boehringer Mannheim) and Rapi Tests (Morwell Diagnostics), EZ-Screen (for cannabis and cocaine), Triage (for benzodiazepines, methadone, and cocaine; Biosite Diagnostic), Abuscreen ONTRAK (for cannabis and morphine; Roche Diagnostics), ONTRAK TESTCUP (for opiates; Roche Diagnostics). There have been many reported limitations for these immunoassay test devices. For cannabinoids, the accuracy varies from 52 to 90%; for opiates 37 to 90%; for amphetamines 44 to 83%, and for cocaine 72 to 92%.¹⁵⁰ Another reported failing of the NPT kits has been the lack of available information about cross-reactivity,¹⁵¹ which is important in drug treatment services where poly substance use is commonplace. Urine samples for use with NPT kits also have the same issues with authenticity as those collected for laboratory-based testing and in addition concern has been raised that without onsite staff training the number of false-positive and false-negative

test results could be unacceptably high. Confirmation of the test result with all initial tests is recommended as good practice.

Most recently, oral fluid immunoassay test kits have also become available (Cozart RapiScan, www.cozart.co.uk) offering a less invasive testing procedure. Oral fluid screening is, however, subject to contamination of the buccal cavity from drugs taken intranasally or sublingually, i.e., cannabis and buprenorphine, respectively. Additionally, the pH of saliva (the main component of oral fluid) can be changed during the sample collection procedure by chewing, which may alter (reduce) the diffusion of the drugs of interest into the oral fluid sample. This could result in false-negative test results. Cost is also prohibitive and currently there is little evidence-based information about these products.¹⁵²

Accurate interpretation of the drug-screening test within a clinical setting, alongside other relevant information, remains the key to the usefulness of any test.

8.1 MEDICAL ASPECTS OF DRUG ABUSE

Shoshana Zevin, M.D.,¹ and Neal L. Benowitz, M.D.²

¹Department of Internal Medicine, Shaare Zedek Medical Center, Jerusalem, Israel

²Division of Clinical Pharmacology and Experimental Therapeutics, University of California, San Francisco, California

Drug abuse is associated with many medical problems and complications stemming both from regular use and from overdoses. Another serious medical complication arising from drug abuse is the withdrawal syndrome, which manifests during abstinence from the drug (see Chapter 7 for a more detailed discussion of withdrawal syndromes).

Drug abuse affects a number of organ systems. Central nervous system (CNS) symptoms can range from headaches and altered mental status to life-threatening situations like coma and seizures (Table 8.1.1 and Table 8.1.2). Cardiovascular manifestations of drug abuse include alterations in blood pressure, heart rate, as well as arrhythmias and organ ischemia. Respiratory arrest, pulmonary edema, and pneumothorax may occur. Metabolic effects such as alterations in body temperature, electrolytes, and acid–base disturbances are commonly seen (Table 8.1.3). Reproductive consequences, ranging from impaired fertility to intrauterine growth retardation, premature births, and neonatal syndromes, may also occur.

Infectious complications from intravenous drug use include viral infections such as HIV and hepatitis B, as well as bacterial infections including bacterial endocarditis, osteomyelitis, and abscesses.

In this chapter we describe the specific clinical syndromes associated with drugs of abuse.

Table 8.1.1 Drugs of Abuse Commonly Causing Altered Mental Status

Hypothermia	Barbiturates
	Benzodiazepines
	Opiates

8.1.1 Stimulants

Stimulant drugs act primarily through activation of the sympathetic nervous system. In moderate doses they result in an elevated mood, increased energy and alertness, and decreased appetite. During intoxication they have profound central nervous system, cardiovascular system, and metabolic effects (Table 8.1.4).

8.1.1.1 Cocaine

Cocaine is one of the most frequent causes of medical complications of drug abuse.^{1–3} Its actions include blockade of reuptake of catecholamines and dopamine by the neurons, release and/or blockade of the reuptake of serotonin, and centrally mediated neural sympathetic activa-

Table 8.1.4 Effects of Stimulant Intoxication

tion.^{4,5} In addition to stimulating the sympathetic nervous system, cocaine also has a local anesthetic effect due to blockade of fast sodium channels in neural tissue and the myocardium.

Cocaine may be injected intravenously, smoked, snorted, or orally ingested. Its half-life is approximately 60 min. After intravenous injection or smoking there is a rapid onset of CNS manifestations; the effects may be delayed 30 to 60 min after snorting, mucosal application, or oral ingestion. The duration of cocaine effect is dependent on the route of administration, and is usually about 90 min after oral ingestion. Acute cocaine intoxication usually resolves after about 6 h, but some manifestations, such as myocardial infarction and stroke, may occur many hours after use, and a cocaine “crash” syndrome may last for several days after cocaine binging.

Most of the toxic manifestations of cocaine are due to excessive central and sympathetic nervous system stimulation. CNS stimulation causes behavioral changes, mood alterations, and psychiatric abnormalities. Autonomic stimulation causes cardiovascular system abnormalities, such as alterations in blood pressure, heart rate, arrhythmias, and hyperthermia (Table 8.1.5). Some of these manifestations, especially in CNS and cardiovascular system, can be life-threatening.

Central Nervous System

In moderate doses cocaine produces arousal and euphoria, but also anxiety and restlessness. Acute intoxication may result in severe psychiatric disturbances, such as acute anxiety, panic attacks, delirium, or acute psychosis.⁶ Chronic cocaine intoxication can produce paranoid psychosis, similar to schizophrenia.⁷ There is evidence suggesting that chronic cocaine use may lead to permanent neurological abnormalities. Brain atrophy, particularly in the frontal cortex and basal ganglia, has been found in chronic cocaine abusers, as well as cerebral blood perfusion deficits in frontal, periventricular, and temporal areas.^{7,8} Abnormalities in cerebral glucose metabolism, as well as reduction in β -ATP/Pi ratios in cerebral cortex, were found in chronic cocaine addicts. These changes are similar to those observed after cerebral hypoxia.⁹

Headache: Headache is quite common in cocaine users, and has been reported in 13 to 50% of the users surveyed. In some patients the headaches were triggered by cocaine, whereas others reported them in association with cocaine withdrawal.^{8,10} Some patients experienced migraine headaches. In some instances, headaches may be induced by hypertension. Persistent headaches, despite normalization of blood pressure, should raise concern about a possible stroke.

Stroke and transient neurologic defects: A variety of neurologic signs have been reported in patients with cocaine intoxication, among them dizziness, vertigo, tremor, and blurred vision. Transient hemiparesis has also been observed, and may be the result of cerebral vasospasm.^{11,12} Strokes are being increasingly recognized in cocaine abuse, particularly in young patients. In one case-control study, the odds ratio for women aged 15 to 44 years who used cocaine or amphetamines was 7.¹³ Among the patients with strokes, about 50% have cerebral hemorrhage, 30% subarachnoid

Table 8.1.5 Medical Complications of Cocaine Intoxication and Abuse

CNS	Headache
	Stroke (ischemic and hemorrhagic)
	Transient neurological deficit
	Subarachnoid hemorrhage
	Seizures
	Toxic encephalopathy
Cardiovascular	Coma
	Hypertension
	Aortic dissection
	Arrhythmia (sinus tachycardia, supraventricular tachycardia, ventricular tachycardia/fibrillation)
	Shock
	Sudden death
Respiratory	Myocarditis
	Myocardial ischemia and infarction
	Other organ ischemia: renal infarction, intestinal infarction, limb ischemia
	Pulmonary edema
	Respiratory arrest
	“Crack lung”
Metabolic	Pneumothorax
	Pneumomediastinum
	Hyperthermia
	Rhabdomyolysis
	Renal failure (myoglobinuria)
	Coagulopathy

hemorrhage, and 20% ischemic stroke.^{8,10,14} This distribution differs from the one found in the general population, where ischemia and not hemorrhage accounts for the majority of strokes. There was also a report of acute subdural hematoma associated with cocaine use.¹⁵ The mechanism of stroke is thought to be an acute elevation of blood pressure induced by increased sympathetic activity, which may cause rupture of cerebral aneurysm; or vasospasm or cerebral vasoconstriction.¹⁶ Interestingly, anticardiolipin antibodies, which are associated with an increased risk of stroke, were found in 27% of asymptomatic cocaine users, and in 5 of 7 cocaine users with thromboembolism.¹⁷ Chronic cocaine abuse has been associated with acute dystonic reactions, which in some cases have been precipitated by neuroleptics, and in others without neuroleptics. Acute dystonia was reported after cocaine use as well as during cocaine withdrawal.^{18,19} Choreoathetoid movements lasting up to 6 days have also been described.²⁰

Seizures: Seizures are seen in about 1.4 to 2.8% of cocaine abusers admitted to a hospital.^{8,10,18,21,22} They are usually generalized, tonic-clonic in character, and may occur soon after taking cocaine, or after a delay of several hours. Seizures may be associated with recreational cocaine use, but are more common in intoxication or “body packer” syndrome.^{8,21} Children can have seizures

as a first manifestation of cocaine exposure.¹⁰ The mechanism of cocaine-related seizures is not clear, and may be related to its local anesthetic properties.

Toxic encephalopathy and coma: Often patients present after several days of cocaine binge; at first they may experience severe anxiety, hyperactivity, and paranoia, which last for about 6 to 8 h, and then may become hypersomnolent and depressed. This latter phase can last 2 to 3 days.

Other complications associated with cocaine abuse are frontal sinusitis and brain abscess after chronic cocaine snorting.²³ Cocaine snorting is also associated with atrophy of nasal mucosa, necrosis, and perforation of the nasal septum.¹⁸

Cardiovascular System

Blood pressure: Intense sympathetic stimulation induced by cocaine results in hypertension and tachycardia. Hypertension is a combined result of increased cardiac output and increased systemic vascular resistance. Hypertension may cause stroke, aortic dissection, and acute pulmonary edema.

Myocardial ischemia: Myocardial infarction has been well documented in cocaine abuse. It is the end result of a combination of several factors including coronary vasospasm, increased myocardial oxygen demand due to increased myocardial work load, and thrombosis.^{24–27} Most patients with cocaine-related ischemia present within 1 h of cocaine use, when the plasma concentrations of cocaine are the highest; however, some patients present hours after cocaine use. The late presentation may be caused by delayed coronary vasoconstriction induced by major cocaine metabolites.^{26,28} However, only between 4 and 6% of patients presenting to emergency room with cocaine-associated chest pain have acute coronary syndrome.^{26,29} Ambulatory electrocardiographic (ECG) monitoring of chronic cocaine users during the first week of cocaine withdrawal demonstrated recurrent episodes of ST segment elevation, probably due to vasospasm.³⁰ Myocarditis presenting as patchy myocardial necrosis has been observed after acute cocaine intoxication, and is believed to result from intense catecholamine stimulation.^{24,30} Clinically, this results in ST segment elevations and/or T wave inversions, with elevated CPK-MB fraction. In chronic cocaine use, the result may be myocardial fibrosis and cardiomyopathy. Other organs may be affected by ischemia resulting from vasoconstriction, including renal infarction and ischemic colitis and mesenteric ischemia,^{31–33} which can be life-threatening. These patients usually present with intense flank or diffuse abdominal pain.

Arrhythmia: Arrhythmia is common in cocaine intoxication; in acute intoxication it results from sympathetic stimulation; and later it may be the result of myocardial ischemia or myocarditis. The most common arrhythmia is sinus tachycardia; other arrhythmias include atrial tachycardia and fibrillation, ventricular tachycardia, including *torsade de pointes* and conduction disturbances due to local anesthetic effects of cocaine, with wide complex tachycardia.³⁰ Ventricular fibrillation can be a cause of sudden death, and asystole has also been reported. QT prolongation was observed in patients after cocaine exposure.³⁴

Shock: Shock may develop in patients with cocaine intoxication as a result of reduced cardiac output due to myocardial ischemia, direct myocardial depression, myocarditis, or arrhythmia, and as a result of vasodilatation due to either local anesthetic effects of cocaine on blood vessels, or its effects on brain stem. Hypovolemia may also be present in agitated and/or hyperthermic patients.

Sudden Death: Most deaths occur within minutes to hours of acute cocaine intoxication, and most are the result of arrhythmia due to either massive catecholamine release or ischemia. Many convulse prior to death. Another syndrome associated with sudden death during cocaine intoxication is “excited delirium,” in which the victim manifests aggressive and bizarre behavior accompanied by hyperthermia, and then suddenly dies.^{35–38} Death due to medical reasons related to cocaine intoxication accounts for about 11% of all cocaine-related deaths; the majority of cocaine-related deaths are due to trauma and homicide.^{14,39}

Pulmonary: Pulmonary edema is a common finding at autopsies of victims of cocaine intoxication. It can occur in acute intoxication either because of myocardial dysfunction or as a result

of a massive increase in the afterload due to vasoconstriction. Noncardiogenic pulmonary edema has also been reported.²⁴ A syndrome called “crack lung” has been described, and consists of fever, pulmonary infiltrates, bronchospasm, and eosinophilia.^{40–42} Alveolar macrophages from crack cocaine smokers were deficient in cytokine production and in their ability to kill bacteria and tumor cells.⁴³ Respiratory arrest can occur as a result of CNS depression. Pneumomediastinum and pneumothorax have been described in patients who snort or smoke cocaine, presumably due to increased airway pressure during a Valsalva maneuver.

Metabolic complications: Severe hyperthermia has been described in patients with acute cocaine intoxication; the mechanism probably is muscular hyperactivity due to agitation or seizures and increased metabolic rate. However, cocaine, even in small doses, was shown to impair sweating and cutaneous vasodilatation, as well as heat perception.⁴⁴ Consistent with these findings, it was found that on hot days (with ambient temperature above 31°C), the number of deaths from accidental cocaine overdose was 33% higher compared to that on days with lower temperatures.⁴⁵ Hyperthermia is also part of the “agitated delirium” syndrome, where it accompanies extremely violent and agitated behavior, in sometimes fatal cocaine intoxications.^{36,37} Victims of the “agitated delirium” syndrome were more likely to be young, male, and black, compared to the victims of accidental cocaine overdose.^{37,38} Hyperthermia, if untreated, can result in brain damage, rhabdomyolysis with renal failure, coagulation abnormalities, and death. Rhabdomyolysis in acute cocaine intoxication is most often the result of muscular hyperactivity and hyperthermia, but can also be due to muscular ischemia due to vasoconstriction. It presents as muscular pains, which can also occur in the chest wall, and must be distinguished from the pain of myocardial ischemia. Lactic acidosis may be a complication of prolonged muscular hyperactivity.

Reproductive/neonatal: Cocaine use during pregnancy can result in an increased incidence of spontaneous abortion, placenta previa, and abruption of the placenta. Placental ischemia results in intrauterine growth retardation.^{46,47} Neonates born to cocaine-addicted mothers have various neurologic abnormalities, including irritability, tremulousness, poor feeding, hypotonia or hypertonia, and hyperreflexia. This syndrome may last for 8 to 10 weeks.^{24,47} There is a dose–response relationship between adverse neonatal effects and maternal cocaine exposure.⁴⁷

Withdrawal: Abstinence after prolonged use of cocaine can result in a “cocaine crash,” manifesting as anxiety, depression, exhaustion, and craving for cocaine. Suicidal ideation is common. The symptoms can last for several weeks to several months after the cessation of use.⁴⁸

8.1.1.2 Natural Stimulants

Ephedrine and khat belong to a group of natural stimulants. Ephedrine is found in a variety of plants, as well as in many Chinese medicines and is part of many nonprescription decongestants. Khat shrub grows in Ethiopia, and khat leaves are chewed in East African countries, particularly in Yemen and Somalia.^{18,49} The active ingredient in khat leaves is (–)cathinone. Both ephedrine and cathinone resemble amphetamine in structure.

Ephedrine

Ephedrine acts directly on alpha and beta-adrenergic receptors, and also stimulates the release of norepinephrine. It exhibits fewer CNS effects compared to amphetamine. Pseudoephedrine is a dextro isomer of ephedrine, and has similar alpha, but less beta-adrenergic activity. Both drugs are marketed as nonprescription medications for nasal decongestion, and are ingredients in many cold medications and bronchodilators. Ephedrine-containing dietary supplements (also known as ma-huang) are widely used for weight loss and energy enhancement. The main manifestations of ephedrine intoxication are cardiovascular, with elevation of blood pressure and heart rate.⁵⁰ Hypertension due to ephedrine intoxication, even if moderate, can result in neurologic complications including headache, confusion, seizures, and stroke, both ischemic and hemorrhagic.⁵¹ There have also been reports of intracerebral

vasculitis and hemorrhage associated with ephedrine abuse.⁵² Severe headache, focal neurologic deficit, or changes in mental status in ephedrine intoxication should raise the possibility of stroke. Fatalities may result from myocardial infarction, arrhythmia, seizures, or stroke.⁵³

Use of dietary supplements containing ephedrine (ma-huang), even in doses recommended by the manufacturer, has been associated with severe cardiovascular events, including myocardial infarction, sudden death, and stroke.^{54,55} Many of the adverse effects occurred in young people without risk factors for cardiovascular disease.

Another, little recognized complication of chronic use of ephedra-containing products is kidney stones, which have been found to contain ephedrine and pseudoephedrine.⁵⁶

Khat

Khat has CNS effects quite similar to amphetamine; but due to the bulkiness of the plant the actual amounts of the active ingredient, cathinone, which is actually ingested, are usually not large. Social use of khat causes increase in energy level and alertness, but also mood lability, anxiety, and insomnia.⁵⁷ Khat abuse may result in mania-like symptoms, paranoia, and acute schizophrenia-like psychosis. In most cases of khat-induced psychosis, heavy khat consumption preceded the episodes.^{49,57,58} Most of the cases are resolved within weeks with cessation of khat use. There is one case report of leukoencephalopathy associated with heavy khat use.⁵⁹ No specific physical withdrawal syndrome is recognized, but there is a psychological withdrawal characterized by depression, hypersomnia, and loss of energy.^{49,57}

Khat intoxication may result in cardiovascular toxicity with hypertension and tachycardia, but severe hypertension has not been observed.^{57,60} Khat chewing may be a precipitating factor for myocardial infarction, probably due to its catecholamine-releasing properties. As compared to non-chewers, khat chewers presenting with acute myocardial infarction were more likely to be young and without cardiovascular risk factors, and were more likely to present during or immediately after khat-chewing sessions.⁶¹

There is an association between khat use and gastric ulcers, and also between its use and constipation, although causation is not clear.⁵⁷

Babies born to khat-chewing mothers are likely to suffer from intrauterine growth retardation. Long-term chewing of khat (for more than 25 years) was found to be strongly associated with oral cancer.⁴⁹

8.1.1.3 Synthetic Stimulants

Amphetamine, along with its analogues methamphetamine and methylphenidate, are sympathomimetics; they act by releasing biogenic amines from storage sites both in the CNS and the peripheral nervous system as well as by directly stimulating alpha- and beta-adrenergic receptors. Thus, they produce CNS stimulation and arousal, and serious mental changes and cardiovascular effects during intoxication.

Amphetamine

Amphetamine is one of the most potent CNS stimulants. It exists as a racemic solution, but dextroamphetamine (D-isomer) is three to four times more potent than levoamphetamine with regard to CNS stimulation. It is mainly administered orally or intravenously. Clinically amphetamine effects are very similar to those of cocaine, but amphetamine has a longer half-life compared to cocaine (10 to 15 h), and the duration of amphetamine-induced euphoria is four to eight times longer than for cocaine.

CNS effects: During acute intoxication with amphetamines, patients commonly present with euphoria, restlessness, agitation, and anxiety.^{18,62} Suicidal ideation, hallucinations, and confusion

are seen in 5 to 12% of the patients with acute intoxication. In one sample of drug users, 55% of amphetamine users reported having at least one adverse effect (anxiety, depression, paranoia, sleep and appetite disturbances).³ Seizures may occur in about 3% of the patients presenting in the hospital with amphetamine intoxication.^{22,62} Stroke has been reported in patients with amphetamine intoxication; it is usually hemorrhagic and results from hypertension.^{13,63,64} There have also been reports of cerebral vasculitis and hemorrhage with chronic abuse of amphetamine.^{65–67} Chronic amphetamine abuse may precipitate psychiatric disturbances, such as paranoia and psychosis that can persist for weeks.^{68,69}

Movement disorders: Chronic high-dose amphetamine use is associated with stereotypic behavior, dyskinesias, and also with chorea, especially in patients with preexisting basal ganglia disorders. Amphetamines exacerbate tics in patients who already have them, and may induce tics, although the causation is unclear.¹⁸

Cardiovascular effects: The major effects seen during acute intoxication are hypertension and tachycardia. Arrhythmia can occur, including ventricular fibrillation. Myocardial ischemia and infarction have been reported; the underlying mechanisms are increased myocardial oxygen demand and/or coronary vasospasm.^{25,62,70,71} Chronic abuse has been reported to result in cardiomyopathy.⁷² Systemic necrotizing vasculitis, resembling periarteritis nodosa, has been associated with chronic amphetamine abuse.⁷³

Metabolic and other effects: Acute amphetamine intoxication can manifest with sweating, tremor, muscle fasciculations, and rigidity. Hyperthermia can develop and may be life-threatening if not treated promptly.⁷⁴ The mechanisms underlying hyperthermia are muscle hyperactivity and seizures. The same mechanisms may also cause rhabdomyolysis with attendant renal failure. Chronic amphetamine abuse can result in weight loss of up to 20 to 30 lb and malnutrition.¹⁸

Withdrawal: Amphetamine withdrawal peaks in 2 to 4 days of abstinence, and can last several weeks. The main symptom is depression, occasionally with suicidal ideation.⁴⁸

Methamphetamine

Methamphetamine is an amphetamine analogue; it has an increased CNS penetration and a longer half-life; its effects may persist for 6 to 24 h longer than amphetamine. It can be ingested orally, smoked, or snorted.⁷⁵ Methamphetamine produces more CNS stimulation with fewer peripheral effects compared to amphetamine,⁷⁶ but large doses may result in hypertension. Stroke, both ischemic and hemorrhagic, has been reported with methamphetamine abuse, and in some cases the stroke was delayed by 10 to 12 h after last use.^{77,78} The mechanisms may be hypertension, thrombosis, vasospasm, and vasculitis. Rhabdomyolysis has also been described in association with methamphetamine abuse.⁷⁹

Methylphenidate

Methylphenidate is structurally related to amphetamine; in therapeutic doses it is a mild CNS stimulant, with more mental than motor effects, and it has minimal peripheral effects in therapeutic doses. It is used clinically for the treatment of attention-deficit disorder and narcolepsy. However, when abused and used in high doses it may cause generalized CNS stimulation with symptoms similar to amphetamine, including seizures. A case of cerebral vasculitis associated with therapeutic doses of methylphenidate was reported.⁸⁰

Phenylpropanolamine

Phenylpropanolamine (PPA) is primarily an alpha-adrenergic agonist, both direct and indirect through release of norepinephrine. It is structurally related to amphetamine. Phenylpropanolamine is an ingredient in many cold and anorectic agents. Phenylpropanolamine combined with caffeine has been sold as a look-alike “amphetamine.” PPA has a low therapeutic index, and doses two to

three times in excess of recommended may result in toxicity. Susceptible individuals, particularly those suffering from hypertension or autonomic insufficiency with attendant denervation hypersensitivity of adrenergic receptors, may experience adverse effects even with therapeutic doses. The main manifestations of phenylpropanolamine toxicity are cardiovascular; however, CNS stimulant effects usually appear at higher doses.

Cardiovascular effects: The main effect of phenylpropanolamine is hypertension due to its alpha-adrenergic properties. Because it has only slight beta-adrenergic activity, there is no tachycardia; rather, a reflex bradycardia is usually present.⁸¹ Patients with phenylpropanolamine-induced hypertension are at risk for stroke, both ischemic and hemorrhagic.^{81–83} A strong association was found between the risk of hemorrhagic stroke in women aged 18 to 49 years and use of phenylpropanolamine-containing appetite suppressants and cold medications. No increase in risk was found in men.⁸⁴ These findings prompted the FDA to remove phenylpropanolamine from over-the-counter medications.^{85,86} Headache is a common feature, and may reflect an acutely elevated blood pressure, or may be the first manifestation of stroke. Patients with a severe headache, altered mental status, or neurologic deficit should be evaluated for stroke even if their blood pressure is not elevated. There are also case reports of chest pain, myocardial infarction, and ECG repolarization abnormalities.⁸¹ The duration of intoxication is about 6 h.

CNS effects: When taken in large doses and/or chronically abused, phenylpropanolamine causes symptoms similar to amphetamine, including anxiety, agitation and psychosis.^{81,87} There are individuals at risk for psychiatric side effects from phenylpropanolamine even at therapeutic doses: these are individuals with past psychiatric history, children younger than 6 years, and post-partum women.^{88,89} Seizures have also been reported, though often when phenylpropanolamine was combined with other drugs, such as caffeine. Case reports of cerebral vasculitis and hemorrhage with phenylpropanolamine use have been described.⁹⁰

8.1.2 Hallucinogens

The primary effects of hallucinogenic drugs are altered perception and mood. The specific effects differ in different drug classes. They are also accompanied by autonomic changes (Table 8.1.6). Most hallucinogens do not induce physical dependence. The specific mechanisms of action are not known for many of the drugs, but there are indications that they act as adrenergic and serotonergic agonists. The changes in mood and perception are probably related to their serotonergic actions.^{91,92} After prolonged or high-dose use of the drugs, there is evidence of depletion of serotonin and dopamine in the neurons in the brain. The psychiatric effects may be quite severe, and require medication. Sometimes the psychosis may be prolonged long beyond the presence of the drug in the body, and there may be chronic psychiatric impairment and memory disturbances, possibly related to damage to serotonergic neurons in the brain.

8.1.2.1 Phenylethylamine Derivatives

Mescaline

Mescaline is a phenylethylamine derivative. Its use probably dates from as long as 5700 years ago.⁹³ It is found in peyote cactus, and can be ingested orally or intravenously. It is structurally related to epinephrine. The precise mechanism of action is unknown, but it is thought to alter the activity of serotonin, norepinephrine, and dopamine receptors.⁷⁶ The signs of intoxication appear within 30 min of ingestion, peak at 4 h, and last 8 to 14 h. The psychic phase lasts about 6 h.⁹⁴ There are both physiological and psychological manifestations of mescaline.

Physiological effects: These are mainly manifestations of autonomic adrenergic activation: dilated pupils, increased sweating, elevated systolic blood pressure and temperature. Large doses of mescaline may induce hypotension, bradycardia, and respiratory depression.⁹⁵ Some users may

Table 8.1.6 Manifestations of Hallucinogen Intoxication and Abuse

Neuropsychiatric:	
<i>Acute</i>	Euphoria
	Altered time perception
	Heightened visual and color perception
	Anxiety
	Disorientation
	Delirium
	Panic attacks
	Suicidal ideation
	Hallucinations

	Cardiovascular collapse
	Respiratory arrest
	Stroke (MDMA)
	Hyperthermia
	Seizures
	Hepatotoxicity (MDMA)
	SIADH (MDMA)

experience nausea, vomiting, or dizziness, which usually resolve within an hour.⁹⁶ A fatal case of Mallory–Weiss lacerations has been described after mescaline ingestion.⁹⁷ Peyote ceremonial tea, which had been stored for a prolonged time, was contaminated with botulism.⁹⁸

Psychological effects: These begin several hours after the ingestion. Typically there is a feeling of euphoria, a sense of physical power, and distortion of sensation. There is an increased color perception.^{95,99} Sometimes there are visual hallucinations, especially of vivid colors. Users may also experience feelings of depersonalization, disorientation, anxiety, emotional lability, and/or emotional outbursts.⁹⁶ There is no physical dependence for mescaline.^{95,99}

TMA-2 (2,4,5-Trimethoxyamphetamine)

TMA is a synthetic analogue of mescaline and amphetamine. It is more potent than mescaline, but resembles mescaline in the effects.¹⁰⁰

DOM/STP (4-Methyl-2,5-Dimethoxyamphetamine)

This is another amphetamine analogue. It has a narrow therapeutic index. Low doses of 2 to 3 mg cause perceptual distortion and mild sympathetic stimulation, but doses two to three times that produce hallucinations and more severe sympathetic stimulation.^{76,101}

PMA (para-Methoxyamphetamine)

This is a very potent hallucinogen and CNS stimulant. Overdose may present with severe sympathetic stimulation including seizures, hyperthermia, coagulopathy, and rhabdomyolysis (like

in amphetamine intoxication) and can result in fatalities.^{102–104} PMA is a more potent CNS stimulant compared to other amphetamines, and there were reports of fatalities where PMA was substituted for MDMA.¹⁰⁴

DOB (4-Bromo-2,5-Dimethoxyamphetamine)

DOB, otherwise called bromo-DOM, is one of the most potent phenylethylamine derivatives; it has about 100 times the potency of mescaline. It is long-acting, with effects starting within an hour, reaching their full strength after 3 to 4 h, and lasting up to 10 h.¹⁰⁵ The manifestations of intoxication are mood enhancement with visual distortion. There are case reports of severely intoxicated patients with hallucinations, agitation, and sympathetic stimulation.¹⁰⁶ DOB, when ingested in large doses, can have an ergot-like effect, and cause severe generalized peripheral vasospasm with tissue ischemia.⁷⁶

MDA (3,4-Methylenedioxyamphetamine)

MDA is an amphetamine derivative included in the category of “designer drugs.” While in small doses it produces mild intoxication with a feeling of euphoria, large doses can cause hallucinations, agitation, and delirium.⁷⁶ It also can produce intense sympathetic stimulation, with hypertension, tachycardia, seizures, and hyperthermia. Death has been reported after MDA use, usually as a result of seizures or hyperthermia.¹⁰⁷

MDMA (3,4-Methylenedioxymethamphetamine)

MDMA is one of the most popular “designer drugs” today, and is used recreationally by a large number of young people.¹⁰⁸ It is also known as “Ecstasy,” “Adam,” and “M&M.” It was “rediscovered” in the 1970s as an adjunct to psychotherapy, but its use for this purpose has since diminished.

Psychological effects: After ingestion of 75 to 150 mg, users experience a sense of euphoria, heightened awareness, improved sense of communication, but also some impairment in the performance of psychomotor tasks.^{95,109} Women tend to have more intense psychoactive effects of MDMA compared to men.¹¹⁰ Acute neuropsychiatric complications have been reported, and include anxiety, insomnia, depression, paranoia, confusion, panic attacks, and psychosis.^{109,111–113} Adverse effects during the 24 h following use include lack of energy, restlessness, insomnia, lack of appetite, and difficulty concentrating.¹¹⁴ Chronic effects of MDMA abuse include depression, drowsiness, anxiety, panic disorder, aggressive outbursts, psychosis, and memory disturbance.^{115–117} The memory disturbance and impaired cognitive performance were found in chronic users who were abstinent, as well as in former users as long as a year after stopping.^{118–123} Although the exact mechanism of action is not known, there is some evidence from animal studies, as well as from human subjects, that MDMA can cause damage to serotonergic neurons in the brain.^{109,124,125} Chronic users of MDMA were found to have lower density of 5-HT transporters in cortex compared to nonusers; there was a dose–response with the extent of use.^{120,126,127} These effects were more pronounced in women compared to men.¹²⁷

Medical effects: Stimulatory effects of MDMA are apparent even in mild intoxication, and include increased blood pressure and heart rate, decreased appetite, and dry mouth. The recreational doses of MDMA significantly increased heart rate and blood pressure.^{128,129} Also common are nausea, vomiting, trismus (jaw clenching), teeth grinding, hyperreflexia, muscle aches, hot and cold flushes, and nystagmus. Additional side effects reported include paresthesias, blurred vision, and motor ticks. There are several reports of MDMA-induced arrhythmias, asystole, and cardiovascular collapse. Other potentially fatal complications include seizures, hyperthermia, and rhabdomyolysis with acute renal failure.^{118,130} There are several case reports of hepatotoxicity, including hepatic failure requiring transplantation, following MDMA ingestion,^{130–134} and several

cases of inappropriate antidiuretic hormone secretion (SIADH) with severe hyponatremia and seizures.^{135–139} CNS complications including stroke (ischemic and hemorrhagic), subarachnoid hemorrhage, and cerebral venous sinus thrombosis have been reported following MDMA ingestion. One syndrome of MDMA intoxication has been reported specifically in the setting of crowding and vigorous dancing, such as in “raves” or clubs. It includes several manifestations: hyperthermia, dehydration, seizures, rhabdomyolysis, disseminated intravascular coagulation, and acute renal failure.^{118,140} This is thought to be the consequence of the combination of sympathomimetic effects including cutaneous vasoconstriction and extreme physical exertion in hot and poorly ventilated conditions, although some features are those of serotonin syndrome.¹⁴¹ There are two case reports of MDMA intoxication, one of them fatal, after regular recreational doses in HIV patients on ritonavir therapy.^{142,143} The mechanism is probably inhibition of CYP2D6, which metabolizes amphetamines, by ritonavir.

Reproductive/neonatal effects: A prospective study following 136 women exposed to MDMA during pregnancy found a significantly increased risk (15.4%) of congenital defects, particularly cardiovascular and musculoskeletal anomalies.¹⁴⁴

MDEA (3,4-Methylenedioxyethamphetamine)

This is an analogue of MDMA, with effects similar to those of MDMA.

8.1.2.2 Lysergic Acid Diethylamide

Lysergic acid diethylamide (LSD) is a synthetic ergoline, and it is the third most-frequently used drug among adolescents, after alcohol and marijuana.^{145,146} The main site of action of LSD is serotonergic receptor 5-HT₂.¹⁴⁷ The effects of LSD, psychological and physical, are dose-related. With oral doses of 20 to 50 µg the onset of effects is after 5 to 10 min, with peak effects occurring 30 to 90 min post-ingestion. Duration of the effects may be 8 to 12 h, and recovery lasts between 10 and 12 h, when normal cognition alternates with altered mood and perception. Cognitive effects include distortion of time and altered visual perception with very vivid color perception. Euphoria and anxiety may be experienced. There are also signs of sympathetic stimulation, with dilated pupils, tachycardia, elevated blood pressure and temperature, and facial flushing. Tremors and hyperreflexia are also common.^{95,148} A “bad trip” may be experienced during LSD intoxication: terrifying hallucinations, which precipitate panic attack, disorientation, delirium, or depression with suicidal ideation. A “bad trip” may occur with first-time use, as well as after recurrent use. Five major categories of psychiatric adverse effects have been described: anxiety and panic attacks, self-destructive behavior, such as attempting to jump out of the window, hallucinations, acute psychosis, and major depressive reactions.¹⁴⁸ Patients who have taken very high doses of LSD have presented with manifestations of intense sympathetic stimulation including hyperthermia, coagulopathy, circulatory collapse, and respiratory arrest.¹⁴⁹ Another danger of LSD abuse is accidents and trauma while trying to drive during intoxication, or during the recovery phase.

There may be chronic toxic effects associated with LSD abuse. Effects that have been described include:

1. Prolonged psychosis, especially among users with preexisting psychiatric morbidity
2. Prolonged or intermittent major depression
3. Disruption of personality
4. Post-hallucinogen perceptual disorder (PHPD)

The last syndrome is characterized by flashbacks, when imagery experienced during LSD intoxication returns without taking the drug. Flashbacks may occur months, and even years, after LSD use. It has been reported that 50% of users experienced flashbacks during the 5 years after their

last use of LSD.^{148–150} In most cases flashbacks occur after LSD has been used more than ten times.¹⁴⁹ Rarely, the flashbacks may be frightening hallucinations; in extreme cases these have been associated with homicide or suicide. Flashbacks may be triggered by stress, illness, and marijuana and alcohol use.^{95,148}

8.1.2.3 Disassociative Anesthetics

Phencyclidine

Phencyclidine (PCP) was developed as an anesthetic, but its psychiatric side effects precluded its use in humans. In the 1960s PCP became a popular street drug. It is most commonly smoked, but can also be ingested orally, snorted, or injected intravenously. PCP is also commonly used as an additive to other drugs, such as marijuana, mescaline, and LSD. The mechanisms of action of PCP include anesthesia without depression of ventilation, and its main site of action is probably blockade of cationic channel of NMDA receptor, as well as sigma opioid receptors.^{151,152} It also inhibits the reuptake of dopamine and norepinephrine, and has direct alpha-adrenergic effects. The effects of PCP are dose-dependent (Table 8.1.7). Smoking causes a rapid onset of effects; the half-life of PCP may range from 11 to 51 h.¹⁵³

Psychiatric effects: At low doses of 1 to 5 mg, PCP produces euphoria, relaxation, and a feeling of numbness. There may also be a feeling of altered body image and sensory distortion. At higher doses there may be agitation, bizarre behavior, and psychosis resembling paranoid schizophrenia. The patients may alternate between agitation and catatonic-like state. There is also analgesia, which may lead to self-injury.^{153,154}

Physical effects: In mild intoxication the most prominent sign is nystagmus, both vertical and horizontal, and numbness in extremities. In severe intoxication there are signs of adrenergic stimulation, with hypertension, tachycardia, flushing, and hyperthermia sometimes complicated by rhabdomyolysis and acute renal failure, and also of cholinomimetic stimulation with sweating,

Table 8.1.7 Manifestations of Phencyclidine Intoxication

Mild (≤ 5 mg)	Confusional state
	Uncommunicative
	Agitated, combative
	Bizarre behavior
	Nystagmus
	Ataxia
	Myoclonus
	Muscle rigidity or catalepsy
	Hypertension
Severe (≤ 20 mg)	Coma
	Eyes may be open
	Myosis
	Nystagmus
	Muscle rigidity
	Extensor posturing, opisthotonus
	Increased deep tendon reflexes
	Hypertension
	Hyperthermia
Massive (500 mg)	Seizures
	Prolonged coma
	Hypoventilation
	Respiratory arrest
	Hypertension
	Prolonged and fluctuating confusional state upon recovery from coma

Source: Modified from Benowitz.¹⁸⁶

hypersalivation, and miosis, and dystonic reactions, ataxia, and myoclonus may also occur. With high doses PCP causes seizures, coma with extensor posturing, respiratory arrest, and circulatory collapse.^{154,155} The eyes may remain open during coma. Coma may be prolonged, even up to several weeks. Death may result directly from intoxication (seizures, hyperthermia) or from violent behavior. Chronic effects of PCP abuse include memory impairment, personality changes, and depression, which may last up to a year after stopping. There is probably no physical dependence on PCP, but after stopping there is craving.

8.1.3 Marijuana

Marijuana is obtained from the *Cannabis sativa* plant; it is a mixture of crushed leaves, seeds, and twigs from the plant. There are many active ingredients in the plant, but the ingredient accounting for the majority of the effects is delta-9-tetrahydrocannabinol (THC). There is a great variability in the amount of THC in different plants and in different batches of marijuana. Hashish is a resinous sap of the *Cannabis* plant, and typically contains 20 to 30 times the amount of THC compared to the equal weight of marijuana. THC exerts its effects through binding to G protein type CB₁ cannabinoid receptors in the brain (CB₂ cannabinoid receptors have been identified in the spleen macrophages and other immune cells). Endogenous cannabinoids, including anandamide and 2-arachidonylglycerol, have been identified.^{156–158} The endogenous cannabinoids produce effects similar to those of THC when administered to animals. Their physiological functions are not yet fully understood, and probably involve neuromodulation of pain and stress and immunomodulation.

Today marijuana is the most commonly used illicit drug in the U.S.^{159–161} Marijuana is usually smoked; one “joint” typically contains 10 to 30 mg of THC; the onset of action is within 10 to 20 min, and the effects last up to 2 to 3 h.¹⁵³ However, during the past 20 years improved cultivation techniques resulted in a greatly increased potency of cannabis products. Today a joint may contain up to 150 mg of THC.^{158,162} Acute effects of marijuana include relaxation and sometimes euphoria, and also perceptual changes, such as enhanced vividness of colors, music, and emotions.^{158,162} There may be a feeling of depersonalization. These effects may last for 2 h or more, depending on the dose. There is impairment of concentration, psychomotor performance, and problem solving. Driving skills may be affected. High doses of THC may cause hallucinations, anxiety, panic, and psychosis.^{153,163,164} These effects can last for several days. Physical effects include impairment of balance, conjunctival infection, increased heart rate, orthostatic hypotension, peripheral vasoconstriction with cold extremities, dry mouth, and increased appetite.^{158,162} There are reports of intravenously injected marijuana extract, which results in rapid onset of nausea, vomiting, fever, and diarrhea, and is followed by hypotension, acute renal failure, thrombocytopenia, and rhabdomyolysis.¹⁶⁵

Chronic users of marijuana have been reported to experience an amotivation syndrome, in which apathy, lack of energy, and loss of motivation persist for days or longer.¹⁶³ Chronic and heavy users of marijuana exhibit impaired performance on tests of memory and attention even after 19-h abstinence.^{166–169} The impaired performance was significantly correlated with the duration of cannabis use.¹⁶⁶ However, it is not clear whether there is any permanent neurological damage, or whether the impairment is due to prolonged release of cannabis from tissues.^{168,169} Chronic use of marijuana may result in inhibition of secretion of reproductive hormones, and cause impotence in men and menstrual irregularities in women.¹⁷⁰ No clear association was found between maternal cannabis use during pregnancy and adverse perinatal outcomes or birth defects, when cigarette smoking and other drug use were taken into account.^{162,171} However, there is a suggestion that *in utero* exposure to marijuana led to deficits in sustained attention and memory between ages 4 and 9.¹⁷²

Chronic smokers of marijuana are at risk for chronic obstructive lung disease, and marijuana tar is carcinogenic and appears to be associated with development of respiratory tract carcinoma and head and neck cancer in young adults.^{41,43,173–177} There are also reports of spontaneous pneumothorax in daily marijuana smokers, although the patients smoked tobacco as well. The mechanism is sustained Valsalva maneuver during forced inhalation.¹⁷⁸

Table 8.1.8 Opiate Receptor Subtypes

Receptor Subtype	Prototype Drug	Major Action
μ_1	All opiates and most opioid peptides	Supraspinal analgesia Prolactin release Cataplexy
μ_2	Morphine	Respiratory depression Gastrointestinal transit Growth hormone release Cardiovascular effects
δ	Enkephalins	Spinal analgesia Growth hormone release
κ	Dynorphin Ketocyclazocine	Spinal analgesia Sedation Inhibition of vasopressin release
ϵ	β -Endorphin	?
σ	<i>N</i> -allylnormetazocine	Psychotomimetic effects

Source: Modified from Olson et al.²⁵⁷

Chronic cannabis use has been shown to lead to the development of tolerance and dependence, and withdrawal syndrome has been demonstrated. About 8 to 10% of cannabis users will develop dependence.^{158,179–182} Cannabis withdrawal syndrome is characterized by restlessness, anxiety, insomnia, anorexia, muscle tremors, and craving for marijuana.^{158,183,184}

8.1.4 Opioids

Opioids have been used and abused since ancient times. They are indispensable in clinical use for pain management, and are also used as cough suppressants and antidiarrheal agents. They are abused for their mood-altering effects, and tolerance and physical and psychological dependence account for continued abuse. Patients who use narcotic analgesics for pain relief may develop physical dependence, but rarely develop psychological dependence on the drug. Opioids are a diverse group of drugs, among them derivatives of the naturally occurring opium (morphine, heroin, codeine), synthetic (methadone, fentanyl), and endogenous compounds (enkephalins, endorphins, and dynorphins). Morphine-like analgesic drugs are also known as narcotics. There are several subtypes of opiate receptors (μ , δ , and κ), which differ in their affinity to different agonists and antagonists, and in their effects (Table 8.1.8). Opiate receptors are present in different concentrations in different regions of the nervous system. Some of the receptors involved in analgesia are located in the periaqueductal gray matter; the receptors believed to be responsible for reinforcing effects are in the ventral tegmental area and the nucleus accumbens. There are opiate receptors in locus ceruleus, which plays an important role in control of autonomic activity; their activation results in inhibition of locus ceruleus firing. After opiate withdrawal there is an increase in locus ceruleus neuronal firing, resulting in autonomic hyperactivity characteristic of opiate withdrawal. Tolerance develops to many of the opiate effects, but differentially to different effects.^{185,186}

In general, opioids cause analgesia and sedation, respiratory depression, and slowed gastrointestinal transit. Severe intoxication results in coma and respiratory depression, which may progress to apnea and death (Table 8.1.9).¹⁸⁷ Adverse side effects from opiates are seen in drug abusers who take an overdose (intentional or unintentional), but also in medical patients who are treated with opiates. Morphine, heroin, methadone, propoxyphene, and fentanyl-derivatives account for about 98% of all opiate deaths and hospital admissions.¹⁸⁸ In the 1990s there was a significant increase in the medical use of opioid analgesics in the U.S. (particularly morphine, fentanyl, hydromorphone, and oxycodone); however, no increase was seen in the emergency department admissions due to abuse of these drugs.¹⁸⁹

Table 8.1.9 Medical Complications of Opiate Intoxication and Withdrawal

Intoxication	
CNS	Stupor or coma Myosis Seizures (propoxyphene, meperidine)
Respiratory	Hypoventilation Cough suppression Respiratory arrest Pulmonary edema
Cardiovascular	Hypotension Bradycardia Conduction abnormalities (propoxyphene)
Metabolic	Hypothermia Cool, moist skin
Withdrawal	
	Anxiety Insomnia Chills Myalgias, arthralgias Nausea, vomiting Anorexia Diarrhea Yawning Midriasis Tachycardia Diaphoresis, lacrimation

Even though different opioid drugs have similar effects, the cross-tolerance is not complete. This is explained by the discovery of different subtypes of mu and delta receptors with differential binding of opioid agonists.^{190–192}

8.1.4.1 Opiate Effects

Analgesic Effects

Opioid receptors μ_1 play a major role in analgesia; analgesic effects are mediated through central, spinal, and peripheral mechanisms. Analgesia is dose-dependent, and in high doses opioids produce anesthesia. Tolerance to analgesic effects develops less rapidly compared to tolerance to mood or respiratory effects.¹⁸⁵

Mental Effects

Mood: Opiate drugs have reinforcing properties, possibly mediated through dopaminergic neuron activation in the ventral tegmental area and nucleus accumbens. Usually, the effect on the mood is relaxation and euphoria; although patients who take opiates for pain relief more often report dysphoria after taking the drug. Tolerance to euphoria-inducing effects develops rapidly.

Sedation: Sedation is dose-dependent, and is often accompanied by stereotypic dreaming.¹⁸⁵ Tolerance develops rapidly. Sedation is a first sign of opiate intoxication; respiratory depression does not occur unless the patient is sedated.

Gastrointestinal Effects

Nausea and vomiting: Nausea and vomiting are prominent side effects of opiates, resulting from their actions on the chemoreceptor trigger zone in the medulla. However, tolerance usually develops to these effects. Different opiates have different likelihood for causing nausea.

Constipation: Opioid drugs decrease gastrointestinal motility and peristalsis, acting in the spinal cord and gastrointestinal tract, thus causing constipation. Tolerance does not develop to this effect, and so constipation persists even in chronic users.¹⁹³ The constipating effect of opiates is used for symptomatic treatment of diarrhea.

Respiratory Effects

Respiratory depression: Respiratory depression is the most serious adverse effect of opiates; it is dose-dependent, and respiratory arrest is almost always the cause of death from opiate overdose. Respiratory arrest occurs within minutes of the intravenous overdose. After overdose from oral, intramuscular, or subcutaneous route, sedation almost always precedes respiratory arrest. Tolerance to respiratory depression develops, but is lost rapidly after abstinence. All opioid agonists produce the same degree of respiratory depression given the same degree of analgesia. The mechanism is through μ_2 receptor stimulation in respiratory centers in the brain stem.¹⁹⁴ Opioids are medically used for the relief of dyspnea in terminally ill patients with cancer; this effect may be also mediated by opioid receptors in the bronchioles and alveolar walls.¹⁸⁷

Pulmonary edema: Pulmonary edema occurs with several opioid drugs, and is noncardiogenic. The precise mechanisms are unknown but probably involve hypoperfusion with tissue injury and cytokine-induced pulmonary capillary endothelial injury. Pulmonary edema is particularly common with heroin intoxication, and may be precipitated by the administration of naloxone (which reverses venodilation and redistributes blood to the central circulation).

Cough suppression: Opiates cause cough suppression by acting in the medulla; the doses needed are usually lower than for analgesia.

Other Effects

Pupillary constriction: Miosis is invariably present in opiate intoxication, unless anoxic brain damage is present.

Pruritus: Pruritis is very common in patients receiving opiates, as well as in addicts. It is caused by histamine release mediated by the μ receptors.¹⁹⁵

Urinary retention: This effect is mediated through spinal cord opiate receptors.¹⁹⁶ Individual narcotic agents have specific effects, which are discussed below.

8.1.4.2 Specific Narcotic Agents

Morphine: Morphine has an elimination half-life of 1.7 h, but its 6-glucuronide metabolite is also pharmacologically active. Morphine can be administered by intravenous, subcutaneous, oral, and rectal routes. While well absorbed, morphine undergoes significant first-pass metabolism when given orally, and thus requires high doses to achieve the desired effects. Although the oral route is the accepted route of administration for pain control in patients with chronic pain, it is not often utilized by drug addicts. Neuroexcitatory side effects, not mediated by opioids receptors, including delirium, myoclonus, seizures, hyperalgesia, and allodynia, have occurred with morphine, and are probably related to the accumulation of metabolites such as morphine-3-glucuronide.^{197,198}

Heroin: Heroin (diacetyl-morphine) is a synthetic derivative of morphine. In the body, it is rapidly converted to 6-acetylmorphine, and then to morphine. The conversion to morphine occurs within minutes. In addition to the effects common to all opiates, there have been reports of acute rhabdomyolysis with myoglobinuria during heroin intoxication.^{199,200} In some case the patients have been comatose, lying with pressure on their muscles, but in other cases rhabdomyolysis occurred with alert patients, accompanied by muscle pains, weakness, and swelling.^{201,202} Chronic abuse of heroin has been associated with progressive nephrotic syndrome resulting in renal failure.²⁰³ The histopathology is focal segmental glomerulosclerosis. There is a broad spectrum of neuropatholog-

ical changes in the brains of heroin abusers. Some are related to prolonged anoxia or vasculitis. Spongiform leukoencephalopathy has been described following inhalation of pre-heated heroin. Two cases of delayed-onset spongiform leukoencephalopathy following intravenous heroin overdose were also reported.^{201,202,204,205} There was also a report of extrapyramidal toxicity after recovery from intranasal heroin overdose.²⁰⁶

Codeine: Codeine, one of the substances found in opium, is about 20% as potent as morphine as an analgesic. It is mostly used as a cough suppressant, and as an ingredient in pain medications. To be effective as an analgesic, codeine must be converted to morphine; this reaction is performed by the isozyme CYP2D6 of the P450 enzymes. The majority of the dose is glucuronidated, and the glucuronide is inactive as an analgesic. The enzyme converting codeine to morphine is subject to genetic polymorphism. About 10% of Caucasians are poor metabolizers, meaning that they do not convert codeine to morphine, and thus do not derive therapeutic benefit from codeine. Inhibition of CYP2D6 resulted in diminished effects of codeine, and caused codeine-dependent patients to use less codeine.^{207,208}

Methadone: Methadone is a synthetic long-acting opiate agonist. It is well absorbed orally, and does not undergo significant first-pass metabolism. It has a half-life of approximately 35 h. Methadone is mainly used as a maintenance therapy for heroin addicts, but occasionally is also used to treat chronic pain. There have been reports of deaths associated with methadone treatment, mostly as a result of too rapid dose increases in subjects who may have lost their tolerance.²⁰⁹

Propoxyphene: Propoxyphene is a derivative of methadone, but unlike methadone, it is only a mild analgesic. It has a half-life of about 15 h, but is metabolized to norpropoxyphene, a potentially toxic metabolite with a longer half-life (about 30 h). Propoxyphene has been associated with a high incidence of toxicity, because in addition to being a respiratory depressant, it also acts as a local anesthetic, and has potent membrane-stabilizing effects. Propoxyphene is an ingredient in many compound analgesics, but it is also abused.²¹⁰ The main cause of death in propoxyphene intoxication is cardiac abnormalities²¹¹ resulting from its membrane-stabilizing effects. Conduction abnormalities with wide QRS that respond to sodium bicarbonate, and cardiovascular collapse have been described.²¹² Seizures have also been associated with propoxyphene intoxication.²¹¹ Unlike respiratory depression, cardiac abnormalities and seizures do not respond to naloxone, since these effects are not mediated through opiate receptors.

Fentanyl: Fentanyl and related drugs are synthetic opioid agonists structurally related to meperidine. Fentanyl is 50 to 100 times more potent than morphine, and has a half-life of about 4 h. Fentanyl is administered intravenously and transdermally, and is used for surgical anesthesia, especially for cardiac surgery; transdermal fentanyl is used for post-operative analgesia and for chronic pain management.²¹³ Fentanyl derivatives that are “street-synthesized” belong to a group of “designer drugs,” and include alpha-methyl-fentanyl (“China White”) and 3-methyl-fentanyl (3MF). Due to the very high potency of fentanyl and related drugs, respiratory depression may occur very rapidly. There are some reports of seizures associated with fentanyl anesthesia,²¹⁴ and a syndrome of delayed respiratory depression with truncal muscular rigidity occurring after recovering from fentanyl anesthesia has been reported.²¹⁵

Hydromorphone: This is a synthetic derivative of morphine that is seven to ten times more potent compared to morphine. Its half-life is 2.5 h. Hydromorphone intoxication presents with all the signs of typical opiate intoxication.

Hydrocodone: Hydrocodone is almost identical to codeine. It is converted in the body to hydromorphone. Like other opiates, it can cause respiratory depression and death.

Oxycodone: This compound is a codeine derivative. Its potency and half-life are comparable to those of morphine. Deaths due to respiratory depression following oxycodone ingestion have been reported.²¹⁶

Oxymorphone: This compound is seven to ten times more potent than morphine. It produces all the signs of classic opiate intoxication.

Meperidine: Meperidine is a synthetic opiate. Its half-life is about 3 h, but its metabolite, normeperidine, has a half-life of 15 to 34 h, and thus accumulates in plasma with repeated dosing.

In patients with renal failure the half-life of normeperidine may be as long as 3 to 4 days. Normeperidine is pharmacologically active, and has both mu-mediated effects as well as other effects not mediated by opioid receptors. Acute intoxication with meperidine presents like morphine intoxication, with respiratory depression, and can be reversed with naloxone. Patients treated with high doses of meperidine, or patients with renal failure, may accumulate high levels of normeperidine resulting in a syndrome characterized by irritability, myoclonus, and seizures.^{217–220} Because of the side effects on the one hand, and lack of any specific benefits on the other, meperidine use has been declining since the 1990s.¹⁸⁹

Pentazocine: Pentazocine is both an opiate agonist and an antagonist. It is an agonist for kappa, delta, and sigma receptors,²²¹ but antagonizes mu receptors. This renders pentazocine less likely to be abused. Pentazocine produces analgesia in nontolerant patients, but may produce withdrawal in tolerant individuals. The action on sigma and kappa receptors probably mediates a psychotomimetic reaction.²²² Pentazocine also potentiates the release of catecholamines from adrenal glands, and in high doses can cause elevated blood pressure and tachycardia.¹⁸⁸ There are two case reports of fibrous myopathy following intramuscular pentazocine abuse.^{223,224}

8.1.4.3 Opiate Withdrawal

Abstinence after prolonged use of opiates results in the opiate withdrawal syndrome (Table 8.1.9). The severity of the symptoms depends on the duration of use and the daily dose of the opiates taken before the cessation of use; it is usually more severe in drug abusers than in patients taking opiates for pain relief. Opiate withdrawal can be precipitated by naloxone, and can occur even after a single dose of an opiate. Acute withdrawal after naloxone usually results in nausea and vomiting, profuse sweating, diarrhea, fatigue, and aches and pains, which may last up to 12 h.²²⁵ During unassisted opiate withdrawal the patient will experience craving for the drug, usually 4 to 6 h after the last administered dose of short-acting opiates such as morphine or heroin (the interval may be 12 to 24 h for methadone). If no drug is administered at this point, there will be a feeling of intense discomfort, with anxiety, agitation, myalgias, sweating, and increased bowel movement. The symptoms will increase over the next 36 to 48 h, reach their peak at 36 to 72 h, and resolve over the next 7 to 10 days. The withdrawal symptoms are not life-threatening. They can be treated specifically with opiate replacement (usually methadone) in doses that will make the patient comfortable, and/or with supportive treatment including clonidine (a central alpha-agonist with some opiate-like effects), or benzodiazepines for anxiety.

8.1.5 Sedative–Hypnotics

8.1.5.1 Benzodiazepines

Benzodiazepines belong to the category of CNS depressant drugs, and are used in clinical practice as sedative–hypnotic and anxiolytic agents. Some benzodiazepines are also used as anti-epileptics and anesthetics. Their principal mechanism of action is potentiation of gamma-aminobutyric acid (GABA) — an inhibitory neurotransmitter — activity in the brain. GABA binds to the receptor opening chloride channels. The influx of chloride ions hyperpolarizes the cell membrane and prevents its firing. Benzodiazepines bind to a different site on the GABA receptor, potentiating the effects of GABA on chloride flux and enhancing the inhibitory effects of GABA.²²⁶ Prolonged use of benzodiazepines results in tolerance. The possible mechanisms are downregulation of the GABA receptors, and configurational changes of the receptor-agonist complex resulting in diminished agonist sensitivity.^{227–229}

There are many drugs in the benzodiazepine class, which share the same pharmacodynamic properties. They differ in their pharmacokinetics, and the differences in elimination half-life and in duration of action indicate their different uses (Table 8.1.10A). Benzodiazepines are classified as

Table 8.1.10A Commonly Used Benzodiazepines

Drug	Elimination Half-Life (h)
Very short-acting	
Triazolam	1.5–3
Midazolam	2–5
Short-acting	
Alprazolam	10–20
Lorazepam	10–20
Oxazepam	5–10
Temazepam	10–17
Intermediate-acting	
Chlordiazepoxide	10–29
Clonazepam	20–30
Diazepam	30–60
Nitrazepam	15–24
Long-acting	
Clorazepate	50–80
Flurazepam	50–100

Table 8.1.10B Commonly Used Barbiturates

Drug	Elimination Half-Life (h)	Duration of Effect (h)
Ultrashort-acting		
Thiopental	8–10	<0.5
Methohexital	3–5	<0.5
Short-acting		
Pentobarbital	15–50	>3–4
Secobarbital	15–50	>3–4
Intermediate-acting		
Amobarbital	10–40	>4–6
Aprobarbital	14–34	>4–6
Butabarbital	35–50	>4–6
Long-acting		
Phenobarbital	80–120	>6–12
Mephobarbital	10–70	>6–12

Source: Adapted from Olson.³³³

very short acting (midazolam), short acting (triazolam), intermediate acting (alprazolam), long acting (diazepam), and very long acting (flurazepam). Most of the benzodiazepines, except oxazepam and lorazepam, which are glucuronidated, are metabolized by liver cytochrome P450 and have active metabolites. Tolerance usually develops to benzodiazepines' effects after continuous use, slowly for long-acting drugs (after about 1 month or more) and more rapidly for short-acting ones. Most users of benzodiazepines obtain the drugs by prescription. Benzodiazepines are abused usually by people who abuse other drugs as well.^{230,231} However, inappropriate chronic use by patients is also common.^{231,232} Because benzodiazepines cause physical and psychological dependence, they are generally recommended for limited periods of time (several weeks) and the doses carefully titrated.^{230,233,234} Side effects of use include daytime drowsiness, aggravation of depression, and memory impairment, especially anterograde amnesia.^{233,235–238} Benzodiazepine use in elderly individuals has been associated with falls and hip fractures, due to drowsiness and ataxia.²³⁹ Chronic benzodiazepine exposure in elderly individuals was associated with functional impairment similar to that caused by medical conditions.²³⁴ However, discontinuation of benzodiazepines results in normalization of memory and psychomotor performance.^{240,241} Short-acting benzodiazepines, in particular triazolam, have been associated with withdrawal symptoms during treatment. The symptoms include rebound insomnia and anxiety when the drug is stopped. The use of triazolam as a hypnotic has also been associated with global amnesia²⁴² and affective and psychiatric disturbances.²³⁶

Intoxication with benzodiazepines results in CNS depression. In general, they have a very high toxic-therapeutic ratio, and doses 15 to 20 times the therapeutic dose may not cause serious side

Table 8.1.11 Manifestations of Sedative–Hypnotic Drug Intoxication and Withdrawal

Intoxication	
Mild	Sedation Disorientation Slurred speech Ataxia Nystagmus
Moderate	Coma, arousable by painful stimuli Hypoventilation Depressed deep tendon reflexes
Severe	Coma, unarousable Absent corneal, gag, and deep tendon reflexes Hypoventilation, apnea Hypotension, shock Hypothermia
Withdrawal	
	Anxiety Insomnia Irritability Agitation Anorexia Tremor Seizures (short-acting benzodiazepines and barbiturates)

Source: Modified from Benowitz.¹⁸⁶

effects. With high doses the patients present with lethargy, ataxia, or slurred speech (Table 8.1.11). With very high doses, and especially when there is co-ingestion of alcohol or barbiturates, coma and respiratory depression may occur. Rapid intravenous injection of diazepam and midazolam may cause respiratory arrest. Respiratory depression has also been reported with short-acting benzodiazepines, particularly triazolam.

Withdrawal: Withdrawal usually occurs after sudden cessation of benzodiazepines; it is usually associated with a prolonged use of high doses, but also after therapeutic doses when the drug was used for several months. The symptoms include anxiety, panic attacks, insomnia, irritability, agitation, tremor, and anorexia (Table 8.1.11). Withdrawal from high doses of benzodiazepines and from short-acting benzodiazepines is usually more severe, and may result in seizures and psychotic reactions.²⁴³ The time course of the withdrawal syndrome depends on the half-life of the specific compound.

8.1.5.2 Barbiturates

Barbiturates are clinically used as sedative–hypnotic drugs, and also for the treatment of epilepsy and induction of anesthesia. They modulate GABA receptor binding sites and potentiate the effects of the inhibitory neurotransmitter GABA. In high concentrations the barbiturates may enhance chloride ion flux independently.²⁴⁴ There are several classes of barbiturates based on their elimination half-life (Table 8.1.10B). The commonly used antiepileptic agent phenobarbital has a half-life of 80 to 120 h. Serious toxicity may occur when the ingested dose is five to ten times the therapeutic. Intoxication with barbiturates results in progressive encephalopathy and coma. Mild intoxication may present as oversedation, slurred speech, ataxia, and nystagmus. Severe intoxication may present with coma, absent reflexes, hypothermia, hypotension, and respiratory depression. Apnea and shock may occur. The time course of intoxication depends on the pharmacokinetics of the specific drug; for phenobarbital coma may last for 5 to 7 days. Barbiturates are usually abused as a “treatment” for unpleasant symptoms of stimulant intoxication; in this context, short-acting drugs, such as pentobarbital and secobarbital, are often used.²⁴⁵

Withdrawal: Withdrawal symptoms upon cessation of barbiturates occur after prolonged use even of therapeutic doses, although severe withdrawal is seen most commonly in polydrug abusers.

The presentation is similar to that of benzodiazepines withdrawal, but there may be a greater risk of seizures with barbiturates withdrawal (Table 8.1.11).

8.1.5.3 Solvents

Solvent abuse has been a problem for many years, particularly among adolescents. The most frequently abused agents are glues, paint thinners, nail lacquer removers, lighter fluids, cleaning solutions, aerosols, and gasoline.^{246,247} The most frequently encountered chemical is toluene, which is an ingredient in glues, paint thinners, and some petroleum products. Other chemicals are acetone in nail lacquer remover, naphtha, fluorinated hydrocarbons, trichloroethylene, and others. The methods of inhalation are breathing the substance from a plastic bag placed directly over the nose or the mouth, inhaling directly from the container or from impregnated rags, and spraying aerosols directly into the mouth. All the solvents are lipid-soluble, and thus easily cross the blood–brain barrier and cell membranes. They typically produce similar effects.

The acute effects of solvent inhalation begin within minutes, and last 15 to 45 min after inhalation. Habitual abusers of solvents may have a rash around the nose and mouth from inhaling, and may have the odor of solvent on their breath.²⁴⁸ The typical effects are feelings of euphoria, disinhibition, and dizziness (Table 8.1.12). There may be also slurred speech, lack of coordination, and impaired judgment.^{248,249} More severe intoxication may result in nausea and vomiting, diarrhea, tremor, ataxia, paresthesia, diffuse pains, and hallucinations. Seizures and coma may ensue.^{247–250} The acute intoxication usually resolves quickly. Toluene abuse has been associated with renal tubular acidosis and severe hypokalemia, as well as interstitial nephritis, and acute tubular necrosis.²⁵¹ There are deaths associated with acute solvent abuse, about half of them the result of accidents such as asphyxiation from the plastic bag. Almost all the rest are thought to be from cardiac causes, including ventricular fibrillation and pulmonary edema.²⁴⁹ Persistent toxic effects have been reported in chronic frequent abusers of volatile substances (Table 8.1.12). These include cerebellar syndrome, parkinsonism, and peripheral neuropathy and cognitive impairments. On magnetic resonance imaging (MRI), cerebral atrophy is seen, particularly in the areas of corpus callosum and cerebellar vermis; SPECT studies have demonstrated areas of hypoperfusion in the brain.^{252–254} Cerebellar syndrome is associated mainly with toluene abuse and presents with nystagmus, ataxia, and tremor. It may be reversible with continued abstinence.²⁴⁸ However, MRI changes demonstrating cerebral and cerebellar atrophy were found.²⁵⁴ There was a report of parkinsonism in a young patient who

Table 8.1.12 Manifestations of Solvent Intoxication and Abuse

Mild	Euphoria
	Disinhibition
	Dizziness
	Slurred speech
	Lack of coordination
	Sneezing and coughing
Moderate	Lethargy, stupor
	Hallucinations
	Nausea, vomiting
	Diarrhea
	Ataxia
	Tremors
	Myalgias
Severe	Paresthesias
	Coma
	Seizures
Chronic	Cerebellar syndrome: ataxia, nystagmus, tremor (toluene)
	Parkinsonism (toluene)
	Peripheral neuropathy: symmetrical, motor, mainly involving hands and feet (<i>n</i> -hexene, naphtha)

chronically abused lacquer thinner; the symptoms persisted for more than 3 months after cessation of use.²⁵⁵ Peripheral neuropathy, predominantly motor and symmetrical, is associated with *n*-hexene and naphtha. Symptoms usually start weeks after the first exposure, and the deterioration may continue for several months after the cessation of solvents. There are reports of hepatitis and liver failure, renal failure, and aplastic anemia associated with chronic solvent abuse.²⁵⁶

8.2 EMERGENCY MANAGEMENT OF DRUG ABUSE

Brett A. Roth, M.D.,¹ Neal L. Benowitz, M.D.,² and Kent R. Olson, M.D.²

¹ University of Texas Southwestern Medical Center, Dallas, Texas

² Division of Clinical Pharmacology and Experimental Therapeutics, University of California, San Francisco, California

The management of complications from drug abuse demands a variety of skills from airway management to control of seizures and shock. Several reviews have addressed the issues of general resuscitation^{1–3} and toxidromes.^{4–8} The purpose of this chapter is to present a series of management strategies for the emergency physician or other clinical personnel caring for patients with acute

complications from drug abuse. Immediate interventions (e.g., resuscitation and stabilization), secondary interventions (e.g., emergency care after the patient is stable), as well as diagnostic workup (e.g., laboratory data, imaging), and disposition of the patient are discussed. This chapter proposes a variety of treatment approaches based on a review of the pertinent literature and clinical experience. A general treatment approach based on symptom complex (i.e., seizures, coma, hyperthermia) is presented since initial management decisions frequently have to be made without the benefit of a reliable history. This is followed by a brief review of the each particular drug of abuse (i.e., psychostimulants, opiates, hallucinogens). The reader is referred to the previous chapter, Medical Aspects of Drug Abuse, for a detailed description of the clinical toxicology associated with each drug of abuse.

It should be emphasized that the adverse reaction to a drug may depend on the unique characteristics of an individual (i.e., presence of cardiovascular disease) as well as the type of drug abused. These protocols serve as guidelines only and an individualized approach to management should be made whenever possible.

8.2.1 Decreased Mental Status: Coma, Stupor, and Lethargy

8.2.1.1 General Comments

In the setting of drug overdose, coma usually reflects global depression of the brain's cerebral cortex. This can be a direct effect of the drug on specific neurotransmitters or receptors or an indirect process such as trauma or asphyxia. Treatment deals largely with maintaining a functional airway, the administration of potential antidotes, and evaluation for underlying medical conditions. The following section describes the appropriate use of antidotes and the approach to the patient with a decreased level of consciousness from drug abuse.

Level vs. content of consciousness: It is often useful to distinguish between the *level* and the *content* of consciousness. Alertness and wakefulness refer to the level of consciousness; awareness is a reflection of the content of consciousness.⁹ In referring to coma, stupor, and lethargy here we address the level of consciousness as it applies to the drug-abusing patient along a clinical spectrum with deep coma on one end, stupor in the middle, and lethargy representing a mildly decreased level of consciousness. Agitation, delirium, and psychosis is addressed in a subsequent section with a greater focus on *content* of consciousness, i.e., presence or absence of hallucinations, paranoia, severe depression, etc.

Attributes of a good antidote: The ideal antidote should be safe, effective, rapidly acting, and easy to administer. It should also have low abuse potential, and act as long as the intoxicating drug. The following standard antidotes are of potentially great benefit and little harm in all patients.

Thiamine: Thiamine is an important cofactor for several metabolic enzymes that are vital for the metabolism of carbohydrates and for the proper function of the pentose-phosphate pathway.¹⁰ When thiamine is absent or deficient, Wernicke's encephalopathy, classically described as a triad of oculomotor abnormalities, ataxia, and global confusion, may result. Although Wernicke's is rare, empiric treatment for this disease is safe,¹¹ inexpensive (wholesale price of 100 mg of thiamine is approximately \$1), and cost-effective.¹²

Dextrose: Hypoglycemia is a common cause of coma or stupor and should be assessed or treated empirically in all patients with decreased level of consciousness. Concerns about 50% dextrose causing an increase in infarct size and mortality in stroke,¹³⁻¹⁵ as well as increasing serum hypertonicity in hyperosmolar patients, have been raised when arguing the benefits of routine administration of 50% dextrose. Animal models of stroke¹⁶ that showed worse outcomes associated with hyperglycemic subjects used large doses of dextrose (approximately 2 mg/kg) as opposed to the 0.3 g/kg (25 g in a 70-kg adult) routinely given as part of the coma cocktail. Also, one ampoule of 50% dextrose in water should only raise the serum glucose level of a 70-kg patient by about 60 mg/dl (0.3 mOsm) if it distributes into total body water prior to any elimination or metabolism.¹⁷

Naloxone: A 19th-century method for treating opiate overdose:

The surface of the body may be stimulated by whipping,... the patient should be made to walk around for 6–8 hours¹⁸

Shoemaker, 1896

Fortunately, the use of modern antidotes such as naloxone can provide a more effective and less abusive reversal of opiate-induced narcosis. In addition to reversing respiratory depression and eliminating the need for airway interventions, naloxone may assist in the diagnosis of opiate overdose and eliminate the need for diagnostic studies such as lumbar puncture and computed tomography (CT) scanning. Despite its advances over 19th-century treatments for narcotic overdose, naloxone may not always be the best approach to management. The risk of “unmasking,” or exposing the effects of dangerous co-ingestions such as cocaine or PCP¹⁹ and of precipitating opiate withdrawal must be considered. The main effects of naloxone include the reversal of coma and respiratory depression induced by *exogenous* opiates, but it also reverses miosis, analgesia, bradycardia, and gastrointestinal stasis.²⁰ Presumably related to the reversal of the effects of *endogenous* opioid peptides, such as endorphins and enkephalins, naloxone has also been reported to have nonspecific benefit (e.g., reversing properties) for the treatment of ethanol, clonidine, captopril, and valproic acid.^{21–24} These “nonspecific” responses are usually not as complete as a true reversal of opiate-induced coma by naloxone. The current literature raises many serious concerns about the safety of naloxone. Pulmonary edema,^{25–30} hypertension,^{31–33} seizures,³⁴ arrhythmias,^{33,35} and cardiac arrest³⁶ have been reported following naloxone administration. In addition, reversing the sedating effects of a drug like heroin may produce acute withdrawal symptoms,³⁷ which, although they are not life-threatening, can cause the patient to become agitated, demanding, or even violent.³⁸ Considering the great number of patients who have received large doses of naloxone as part of controlled trials for shock,^{39–42} stroke,^{43–46} and spinal cord injuries,^{47–49} as part of healthy volunteer studies,^{50,51} and for overdose management,^{52,53} all without significant complications, the use of naloxone appears relatively safe.¹⁷ Opioid withdrawal symptoms commonly occur in addicted patients given naloxone.³⁷ While withdrawal symptoms are treatable, the best approach is avoidance. Withdrawal symptoms may be avoided either by (1) withholding opioid antagonists from known drug addicts and supporting the airway with traditional methods (e.g., endotracheal intubation) or (2) by titrating the dose of naloxone slowly such that enough antidote is given to arouse the patient but not to precipitate withdrawal. The latter can be done by administering small doses (0.2 to 0.4 mg) intravenously in a repetitive manner. While conjunctival⁵⁴ and nasal^{55,56} testing for opioid addiction have been described, these tests are impractical in the patient with altered mental status in whom immediate action is necessary.

Nalmefene: Nalmefene ($t_{1/2}$ = 8 to 9 hours) is a methylene analogue of naltrexone that, like naloxone, is a pure opioid antagonist. It was developed to address concerns about the short duration of action of naloxone (~60 min). Studies have proved it to be as safe and effective with a duration of action at least twice as long as naloxone.⁵⁷ Other reports suggest a duration of action of up to 4 h.^{57–59} However, 4 h is still not long enough to safely manage patients who have overdosed on long-lasting opiates such as methadone ($t_{1/2}$ up to 48 h) or propoxyphene ($t_{1/2}$ of active metabolite up to 36 h), or in those patients with delayed absorption. The use of nalmefene may potentially be advantageous due to (1) less risk of recurrent respiratory depression in the patient who leaves the emergency department against medical advice, (2) fewer doses of antagonist needed, cutting down on nursing time, and (3) fewer complications resulting from fluctuations in levels of consciousness (e.g., sedation, aspiration, occult respiratory insufficiency).⁶⁰ The dose is 0.25 to 1.0 mg IVP, with the lower dose recommended to avoid opiate withdrawal. The disadvantage of nalmefene is its cost (average wholesale price of nalmefene is \$31.21/1 mg versus \$5.52/0.4 mg of naloxone). Current use of nalmefene has been limited to the reversal of procedural sedation,⁶¹ alcohol dependence,⁶² and avoidance of opiate side effects in patients receiving epidural analgesia.⁶³

Flumazenil: Flumazenil is a highly selective competitive inhibitor of benzodiazepines at the GABA/benzodiazepine-receptor complex.⁶⁴ Like naloxone it is a pure antagonist lacking agonist properties or abuse potential. It has been shown to be safe and effective for the reversal of benzodiazepine-induced sedation in volunteer studies⁶⁵ and in patients undergoing short procedures such as endoscopy.^{66–70} There has been some debate about the role of flumazenil in the treatment of patients presenting with an acute drug overdose. Although initially recommended with caution for this population,^{71,72} recent advice would be to administer it only when there is a reliable history of benzodiazepine ingestion and the likelihood of a significant proconvulsant or proarrhythmic coingestion or benzodiazepine dependency is limited. Adverse effects including precipitation of benzodiazepine withdrawal,^{73,74} seizures,^{75–78} ballism,⁷⁹ arrhythmias,^{80,81} and even death^{82,83} have occurred. In a review of 43 cases of seizure activity associated with flumazenil administration, 42% of the patients had ingested overdoses of cyclic antidepressants.⁷⁵ In addition to patients with concurrent cyclic antidepressant poisoning, *high-risk populations* include patients who have been receiving benzodiazepines for a seizure disorder or an acute convulsive episode, patients with concurrent major sedative–hypnotic drug withdrawal, patients who have recently been treated with repeated doses of parenteral benzodiazepines, and overdose patients with myoclonic jerking or seizure activity before flumazenil administration.⁷⁵ To minimize the likelihood of a seizure, it is recommended that flumazenil not be administered to patients who have used benzodiazepines for the treatment of seizure disorders or to patients who have ingested drugs that place them at risk for the development of seizures⁷⁵ (e.g., cyclic antidepressants, cocaine, amphetamines, diphenhydramine, lithium, methylxanthines, isoniazid, propoxyphene, bupropion HCl, etc.). As with naloxone, flumazenil may also uncover the effects of a more serious intoxication such as cocaine making the patient unmanageable. Because benzodiazepine overdoses are associated with only rare mortality⁸⁴ and only mild morbidity (the major complication being aspiration pneumonia),⁸⁵ a conservative approach with supportive airway maneuvers (e.g., endotracheal intubation) seems safest. Despite concerns over side effects, the use of flumazenil in patients with acute overdose is justified under certain circumstances. When there is a reliable history of a single drug ingestion supported by clinical manifestations consistent with benzodiazepine intoxication, and the likelihood of a significant proconvulsant or proarrhythmic co-ingestion or benzodiazepine dependency is limited, reversal of sedation may be warranted.¹⁷ One case report described continuous flumazenil infusion for 16 days without adverse effects for clonazepam-induced sedation.⁸⁶ Errors can be avoided by obtaining a thorough history and by performing a thorough physical examination as well as a screening electrocardiogram to exclude the possibility of significant cyclic antidepressant intoxication; correction of hypoxia, hypotension, acidosis, and arrhythmias; and then by administering the agent slowly. Greenblatt⁸⁵ showed that of 99 cases in which patients overdosed on benzodiazepines only 12 were known to ingest benzodiazepines alone. Given the high incidence of co-ingestions in the drug-abusing population the risk for unmasking proconvulsants such as cocaine or amphetamine must be considered high. It is interesting that flumazenil has been credited with the reversal of paradoxical benzodiazepine-induced agitation⁸⁷ and hepatic encephalopathy⁸⁸ and that it is being investigated as a treatment aid for benzodiazepine withdrawal.⁸⁹

8.2.1.2 Stepwise Approach to Management

Immediate Interventions

1. Airway, Breathing, Circulation: Maintain the airway and assist ventilation if necessary. Administer supplemental oxygen. Treat hypotension, and resuscitate as per previous reviews.^{2,90}

2. Thiamine: Administer thiamine, 100 mg IVP over 2 min to all the following patients:

- a. Patients with altered mental status if the patient has signs or symptoms of Wernicke's encephalopathy

- b. Patients who are malnourished⁹¹
- c. Patients with a history of alcoholism¹⁰
- d. Patients with prolonged history of vomiting⁹²
- e. Patients who are chronically ill⁹³

Comment: There is no need to withhold hypertonic dextrose (D₅₀, D₂₅) until thiamine administration since thiamine uptake into cells is slower than the entry of dextrose into cells.⁹⁴ Previous reports describing adverse reactions to IV thiamine⁹⁵ have recently been disputed. In a review by Wrenn et al.¹¹ the incidence of adverse reactions to IV thiamine ($n = 989$) was 1.1% and consisted of transient local irritation in all patients except one who developed generalized pruritis. Thiamine may also be administered intramuscularly (IM) or by mouth (po).

3. Dextrose

Bedside fingerstick glucose level: Perform rapid bedside testing in all patients. If hypoglycemia is detected then the patient should receive hypertonic dextrose (25 g of 50% hypertonic dextrose solution IVP).

Comment: This approach avoids giving dextrose solution to patients who do not need it (eliminating concerns that hyperglycemia impairs cerebral resuscitation) and detects the vast majority of hypoglycemic patients. Relying on physical signs and symptoms such as tachycardia and diaphoresis in combination with a history of diabetes mellitus is an unreliable way to predict hypoglycemia, missing up to 25% of hypoglycemic patients.¹⁷

Borderline rapid assay results: In any patient with borderline rapid assay results (60 to 100 mg/dl) a decision on whether or not to treat should be based on the clinical suspicion of hypoglycemia and a repeat rapid assay. Alternatively, simply treat all patients with borderline blood sugar results.

Comment: Rapid reagent assays for blood glucose may, at times, be inaccurate. Failure to detect hypoglycemia has been described in 6 to 8% of patients tested in the prehospital setting,^{96,97} but results are generally more accurate inside of the hospital. False-negative results have also been reported in neonatal populations⁹⁸ and in patients with severe anemia.⁹⁹ False-positive tests (false hypoglycemia) has occurred in patients with severe peripheral vascular disease,¹⁰⁰ shock,¹⁰¹ and hyperthermia.¹⁰² Because most errors occur in patients with borderline glucose readings (60 to 100 mg/dl),¹⁷ the recommendation to treat borderline glucose values is made. This also makes sense in light of recent reports that describe individual variability in response to borderline hypoglycemia;¹⁰³ e.g., patients with poorly controlled diabetes mellitus may experience clinical symptoms of hypoglycemia at greater glucose concentrations than nondiabetics.

Empiric treatment: In patients where rapid bedside testing for serum glucose is not available, administer 25 g of 50% hypertonic dextrose solution IVP after collecting a specimen of blood for glucose analysis at a later time.

4. Naloxone/Nalmefene:

- a. **Restraint:** Consider restraining and disrobing the patient prior to administration.
- b. **Antidote:** All patients with classic signs (RR < 12, pupils miotic, needle marks) and symptoms of opioid intoxication should receive naloxone.

Comment: Because of nalmefene's expense, naloxone is generally recommended. Nalmefene may be advantageous in the patient who leaves the emergency department against medical advice or if close monitoring of the patient is not possible. The usual initial dose is 0.25 mg IV followed by repeated doses until adequate response is achieved.

Comment: Hoffman et al.,¹⁰⁴ using a clinical criteria of respiratory rate less than 12 breaths/min, circumstantial evidence of opioid abuse, or miosis, decreased the use of naloxone by 75 to 90% while still administering it to virtually all naloxone responders who had a final diagnosis of opiate overdose.

- c. **Initial Doses:** Small doses (0.2 to 0.4 mg IV of naloxone) should be given to patients who are breathing, and at possible risk for withdrawal. If no response, repeat or titrate the same dose IV every minute until 2.0 mg of naloxone or 1.0 mg of nalmefene have been given or the patient wakes up.

Table 8.2.1 Half-Lives and Observation Times Required after Acute Narcotic Overdose

Opioid	Duration of Action via IV Route	$t_{1/2}$	Observation Time (h)
Propoxyphene (Darvon, Doloxene)	May be >24 h	6-12 ^a	24
Methadone (Dolophine, Amidone)	May be days	15 ^b -72 ^c	24-36 or longer
Morphine	Usually 2-4 h	3	6
Heroin	Usually 2-4 h	Very short ^d	6
Fentanyl (Sublimaze)	Minutes	4	6
Codeine	2-4 h (oral)	3 ^d	6
Meperidine (Demerol)	2-4 h	2.5	6
Pentazocine (Talwin)	2-4 h	2	6
Dextromethorphan	2-4 h (oral)	6-29	4

Note: Generally, if patients remain asymptomatic 6 h after the administration of naloxone, they may be discharged.

^a About 1/2 of dose is metabolized to norpropoxyphene, an active metabolite with a $t_{1/2}$ of 30-36 h.

^b Single dose.

^c Repeated dosing.

^d Rapidly deacetylated to morphine.

Comment: If the patient is not suspected to be at risk for opiate withdrawal (i.e., most children) and there is no risk of unmasking a dangerous co-intoxicant such as cocaine or phencyclidine (PCP), 2.0 mg of naloxone may be given initially.

- d. High-dose antidote:** If there is still no response to a total of 2.0 mg of naloxone and opiate overdose is highly suspected by history or clinical presentation, one can give 10 to 20 mg of naloxone in one bolus dose. Certain opiates (i.e., propoxyphene, pentazocine, diphenoxylate, butorphanol, nalbuphine, codeine) may require larger doses of naloxone due to higher affinity for the kappa receptors.¹⁰⁵

Comment: Reversal of opioid toxicity, once achieved, will be sustained for approximately 20 to 60 min ($t_{1/2} = 1$ h). Because the duration of action of most opioids exceeds the duration of action of naloxone, the patient may require repeated bolus doses or to be started on a continuous infusion at a dose sufficient to prevent the reappearance of respiratory depression (see Section 8.2.10.2 on opiates).

Comment: A true response to naloxone or nalmefene is a dramatic improvement. Anything less should be considered a sign of a coexisting intoxication or illness, a nonspecific improvement from the reversal of endogenous opiates, or the presence of anoxic encephalopathy from prolonged respiratory depression. If dramatic improvement is noted, further management depends on the type on narcotic involved and the amount taken (Table 8.2.1).

- e. Dose in respiratory arrest:** Patients with respiratory arrest should either be given larger doses (0.4 to 2.0 mg of naloxone) or endotracheally intubated and artificially ventilated.

Comment: Naloxone is easily administered via the IV, IM, intratracheal,¹⁰⁵ intralingual,¹⁰⁶ or even the intranasal⁵⁶ routes. The intravenous route is preferred since it allows more exact titration and because it provides for a rapid onset of action (about 1 min) and predictable delivery of drug. The intramuscular route (1.0 to 2.0 mg) usually works within minutes, but makes titration more difficult and takes longer to work (5 to 10 min). It may be advantageous in the prehospital setting. The intralingual route, with antidote given near the venous plexus on the ventral lateral tongue, may work as rapidly as the intravenous route, but does not allow for titration of dosage.

- f. Aspiration:** Guard against aspiration.

5. Flumazenil

- a. Caution:** Because of a higher incidence of severe adverse effects flumazenil should be used only under the limited circumstances described previously.
- b. Restraint:** Consider restraining and disrobing the patient prior to administering antidote.
- c. Antidote:** If a pure benzodiazepine overdose is suspected, treat hypoxia, hypotension, acidosis, and arrhythmias and check a 12-lead electrocardiogram (ECG) for QRS widening. If the ECG is

normal, and the patient has no known seizure disorders, *and* is not taking proconvulsant medications, flumazenil may be administered.

Comment: Generally flumazenil should be used only to reverse serious respiratory depression. Its use is not advised to waken a stable, mildly somnolent patient. If serious respiratory depression does exist, consider endotracheal intubation and mechanical ventilation as an alternative to flumazenil.

Comment: In a study of 50 patients treated with flunitrazepam ($t_{1/2} = 20$ to 29 h) Claeys et al.¹⁰⁷ showed that 90 min after administration of flumazenil significant recurrent sedation was observed in healthy patients undergoing orthopedic surgery. Because the binding of flumazenil to the benzodiazepine-receptor complex is competitive, and because flumazenil has a much shorter duration of action ($t_{1/2} = 40$ to 80 min) than most benzodiazepines, patients should be closely monitored for resedation.

- d. **Dose:** Give flumazenil 0.2 mg over 30 s, to be followed 30 s later by 0.3 mg if the patient does not respond. Subsequent doses of 0.5 mg may also be given although most patients respond to less than 1.0 mg.¹⁰⁸ Although the manufacturers recommend the administration of up to 3 mg we recommend a maximal dosage of 1.0 mg in the drug-abusing patient at high risk for withdrawal.

Comment: As long as flumazenil is administered slowly with a total dose of less than 1 mg, only 50% of benzodiazepine receptors will be occupied by the drug.¹⁰⁹ In theory, this should prevent the severe manifestations of withdrawal associated with higher doses.¹⁷

Secondary Interventions

1. Reassess: If the patient remains comatose, stuporous, or lethargic despite antidotes, reassess for underlying medical causes (meningitis, trauma, epilepsy, etc.) and admit to hospital.

2. Monitor: Maintain continuous monitoring (cardiac status, oxygen saturation, blood pressure) at all times.

Comment: This is particularly important since the duration of action of most narcotics and benzodiazepines of abuse is much longer than the duration of action of their respective antidote.

3. CT/lumbar puncture: Consider CT and lumbar puncture if the patient is febrile or has persistently decreased level of consciousness or focal neurological findings.

4. ECG: Perform an ECG on all elderly patients.

5. Laboratory Data: For patients who respond to antidotes and return to their baseline mental status within an observation period of several hours, no laboratory testing may be necessary given a normal physical examination on reassessment. If the patient remains persistently altered or has significantly abnormal vital signs check electrolytes, CBC, CPK, CPK-MB, renal function, and possibly hepatic function. While the use of toxicology screens of blood and urine are generally overutilized,⁵ they are recommended if the diagnosis remains questionable.

6. Disposition

Admission: All patients who have required more than one dose of antidote to maintain their mental status should be admitted for further evaluation and therapy including possible infusion of naloxone or flumazenil.

Comment: Infusions should be maintained in an *intensive care setting* and patients should be closely monitored any time the infusion is stopped. Duration of observation depends on the route of drug administration, the drug ingested, the presence or absence of liver dysfunction, and the possibility of ongoing drug absorption from the gastrointestinal tract. Usually 6 h is adequate.

Flumazenil infusion: Infuse 0.2 to 0.5 h in maintenance fluids (D5W, D51/2NS, 1/2NS, NS), adjusting rate to provide the desired level of arousal. Hojer et al.¹¹⁰ demonstrated that infusions of 0.5 mg/h were well tolerated and that this dose prevented patients with severe benzodiazepine poisoning from relapsing into coma after arousal with a single bolus injection.

Naloxone infusion: Goldfrank et al.¹¹¹ suggest taking two thirds the amount of naloxone required for the patient to initially wake up and administering that amount at an hourly rate in the patient's maintenance IV (D5W, D51/2NS, 1/2NS, NS). Based on the half-life of naloxone this regimen will

maintain the plasma naloxone levels at or greater than those that would have existed 30 min after the bolus dose.^{111,112}

Example: The patient responds to 3 mg of naloxone initially. Add 20 mg naloxone to 1 L maintenance fluids and run at 100 cc/h thus delivering 2 mg naloxone/h (e.g., 2/3 the initial dose per hour).

7. Discharge: Stable patients who have regained normal mental status and have normal (or near normal) laboratory data may be observed for a period of time, which depends on the drug ingested (see Table 8.2.1 for recommended observation period after opioid overdose) and underlying conditions. Usually if the patient is awake and alert 6 h after administration of antidote, the patient may be safely discharged if there is no further drug absorption from the gastrointestinal tract.

8.2.2 Agitation, Delirium, and Psychosis

8.2.2.1 General Comments

Confounders: Rapid control of drug-induced agitation, delirium, or psychosis is one of the most difficult skills to master when dealing with complications of drug abuse. The use of sedation and restraints is fraught with a host of ethical and legal issues.^{113–116} Safety issues for the patient as well as the medical staff must be considered. Numerous reports of injuries to emergency department personnel^{117,118} exist. Diagnostic confusion may occur since agitation or delirium may be the result of a drug overdose alone, or may be from a medical problem combined with drug intoxication (i.e., myocardial infarction from cocaine abuse), or simply a medical problem masquerading as drug abuse (i.e., meningitis). Finally, failing to understand the differences between agitation, psychosis, and delirium (see following discussion) often leads to incorrect management schemes. Regardless of the cause, effective, compassionate, and rapid control of agitation is necessary to decrease the incidence of serious complications and to provide a thorough evaluation of the patient. One can never safely say that the patient was “too agitated” or “too uncooperative” to assess.

Delirium vs. psychosis with and without agitation: Altered sensorium (disorientation and confusion) and visual hallucinations are characteristic of *delirium*. In contrast, *psychosis* is associated with paranoia, auditory hallucinations, and usually an intact sensorium.⁵ *Agitation* (physical or psychic perturbation) may complicate either delirium or psychosis and is commonly seen in patients with stimulant overdose. Differentiating between delirium and psychosis with or without agitation and agitation alone is useful because it may suggest specific groups of drugs and potentially, specific treatment.⁵ For example, a patient with anticholinergic poisoning from Jimson weed typically has delirium with confusion and disorientation, while an amphetamine- or cocaine-intoxicated person usually has paranoid psychosis with agitation, but is oriented. Physostigmine is useful in the diagnosis of anticholinergic syndrome,¹¹⁹ but would not be helpful for amphetamine- or cocaine-induced agitation. Agitation from stimulants should be treated with benzodiazepines, while psychosis alone can be treated with haloperidol with or without benzodiazepines.

Benzodiazepines vs. neuroleptics: There is significant controversy regarding the optimal choice of sedating agents. Much research has dealt directly with agitated patients in the psychiatric setting,^{120–122} but no controlled clinical studies of benzodiazepines or neuroleptic medications in treating strictly drug-induced agitation have been described. Animal research^{123–125} and human experience¹²⁶ support the use of *benzodiazepines* for cocaine-induced agitation as well as generalized anxiety.^{127,128} Neuroleptics (e.g., haloperidol) have been shown to decrease the lethal effects of amphetamines in rats^{129–131} and chlorpromazine was found to be effective in treating a series of 22 children with severe amphetamine poisoning.¹³² Many of the children exhibited seizures before receiving chlorpromazine, but ongoing motor activity was reduced in all cases. These data are consistent with the observation that chlorpromazine antagonizes cocaine-induced seizures in dogs.¹²³ Callaway et al.¹³³ argue that neuroleptics have been used safely in other patient populations at risk

for seizures, such as the treatment of alcoholic hallucinosis during alcohol withdrawal.¹³⁴ Concerns about neuroleptics potentiating drug-induced seizures may therefore be exaggerated. Butyrophenone neuroleptics such as haloperidol have less effect on seizure thresholds than do phenothiazines such as chlorpromazine¹³⁵ and also produce less interference with sweat-mediated evaporative cooling (e.g., anticholinergic effect) in cases of drug-induced hyperthermia.¹³³ Hoffman¹³⁶ has argued against the use of haloperidol for cocaine intoxication on the basis of controlled animal studies showing haloperidol failed to improve survival, and *possibly* increased lethality.¹³⁷ He also argues that haloperidol causes a variety of physiologic responses that limit heat loss. These include (1) presynaptic dopamine-2 (D_2) receptor blockage, causing a loss of inhibition of norepinephrine release and increased central and peripheral adrenergic activity; (2) hypothalamic D_2 blockade causing direct inhibition of central heat dissipating mechanisms; and (3) anticholinergic effects causing loss of evaporative cooling via loss of sweat. The risk of a dystonic reaction, which has been associated with fatal laryngospasm^{138,139} and rhabdomyolysis,¹⁴⁰ is also of concern. Acute dystonia, which is more common in young males,¹⁴¹ could severely impair a resuscitation attempt and may aggravate hyperthermia. Interestingly, the incidence of dystonic reactions from neuroleptic agents has been shown to be dramatically reduced when benzodiazepines are coadministered.¹⁴² Recently the use of the atypical antipsychotic agent ziprazidone has been recommended for controlling acute psychotic agitation. Although study populations are mixed, they are primarily composed of psychiatric patients with functional, as opposed to drug-induced psychosis. Nevertheless, ziprazidone has not been associated with hyperthermia, dystonia, nor the anticholinergic effects of haloperidol. Studies suggest beneficial effects similar to lorazepam or haloperidol with less sedation.^{143–145}

Recommendations: Because of the complex neuropharmacology associated with agitation, delirium, and psychosis in the drug abusing patient our preference is a selective approach based on symptom complex:

Severe agitation: In cases of severe agitation, regardless of underlying delirium or psychosis, we recommend starting with benzodiazepines due to their proven safety and known ability to increase the seizure threshold. They should be given in incremental doses until the patient is appropriately sedated and large doses should not be withheld as long as the blood pressure remains stable and the airway is secure. If respiratory depression occurs, the patient should be endotracheally intubated and mechanically ventilated.¹³⁶

Psychosis: If severe agitation includes marked psychotic features or there is known amphetamine or amphetamine-derivative overdose (i.e., 3,4-methylenedioxymethamphetamine or MDMA), or if the major symptom complex has psychotic features, then haloperidol may be used. Due to synergistic effects¹²² and to decrease the incidence of dystonic reactions,¹⁴² haloperidol should be administered in combination with a benzodiazepine. Anticholinergic agents (i.e., benztropine) reduce the incidence of dystonic reactions;¹⁴⁶ however, because of the potential to confuse an anticholinergic syndrome with psychosis¹⁴⁷ and because anticholinergic agents limit heat dissipation, they are not routinely recommended.

Delirium: As long as agitation is not prominent the administration of low dose benzodiazepines, or observation alone, is usually adequate to control symptoms of mild delirium until drug effects wear off. Intramuscular ziprazidone may also be considered in this setting. In selected anticholinergic poisonings involving uncontrollable agitation or severe hyperthermia, physostigmine (0.5 to 1.0 mg slow IV push) should be considered.¹⁴⁸ Physostigmine may potentiate the effects of depolarizing neuromuscular-blocking agents (e.g., succinylcholine decamethonium)^{149,150} and may have additive depressant effects on cardiac conduction in patients with cyclic antidepressant overdose.^{151,152} Its use is therefore contraindicated in patients with tricyclic antidepressant poisoning and poisoning that impairs cardiac conduction. Physostigmine may induce arousal in patients with benzodiazepine or sedative-hypnotic intoxication¹⁵³ due to its nonspecific analeptic effects.

A word of caution: Control of agitation, delirium, and psychosis is important, but even more important is the treatment of the underlying cause. Algorithms for detecting hypoxia, hypotension, and hypoglycemia still apply. In the mentally unstable patient, who will not allow evaluation or examination, physical restraint and the liberal use of benzodiazepines (see below) may be necessary.

8.2.2.2 Stepwise Approach to Management

Immediate Interventions

1. Airway, Breathing, Circulation: Maintain the airway and assist ventilation if necessary. Administer supplemental oxygen. Treat hypotension, and resuscitate as per previous reviews.⁹⁰

2. Antidotes: Administer appropriate antidotes, including 25 g dextrose IV if the patient is hypoglycemic, as per the section on coma. If the patient does not allow assessment and stabilization, proceed as follows (once the patient is under control, reassess the need for antidotes).

3. Reduction of environmental stimuli: If possible attempt calming the patient by eliminating excessive noise, light, and physical stimulation. Generally, this is all that is necessary for the treatment of panic attacks from mild cocaine overdose, or from certain hallucinogens such as LSD or marijuana.^{148,154} Talk to the patient and attempt to address the patient's immediate needs (minor pain, anxiety, need to use the bathroom). An offer of food or water may calm the patient and avoid further confrontation. Gay et al.¹⁵⁴ from the Haight-Ashbury Free Medical Clinics, in San Francisco, have described the "ART" technique as a way of establishing credibility with the intoxicated patient:

A = Acceptance. Acceptance disarms patients who may already be experiencing fear of their surroundings or paranoid ideation.

R = Reduction of stimuli, rest, and reassurance. If patients are stable and symptoms are mild, place them in a quiet surrounding, and reassure them that they are going to be all right as you proceed to assess them. If patients are dangerous or seriously ill, control them with physical and/or medical restraints (see following section). When stable, proceed to eliminate any source of obvious distraction or distress (too many people in the resuscitation room, bright lights, loud noises, etc.).

T = Talkdown technique. Use verbal sincerity, concern, and a gentle approach since drug abusers can misinterpret insincere and/or abrupt actions as being hostile. If patients are obviously beyond reason or dangerous *do not attempt to "talk them down."* Generally, this step should be restricted to patients who are oriented and simply frightened. It is also *not* recommended for patients who have taken phencyclidine (PCP) due to the unpredictable effects of this drug.¹⁵⁵ Staff members should be careful to never position themselves with a potentially violent or distraught patient between them and the door.

4. Sedation: Medical management may be necessary if the patient remains uncooperative. Explain to the patient your intention to use medications.

5. Paralysis: If significant hyperthermia occurs as a result of excessive muscular hyperactivity, or if significant risk for spinal injury is present, consider early skeletal muscle paralysis (see discussion under hyperthermia). Procedures for the rapid sequence induction for airway management and paralysis are reviewed elsewhere.²

6. Physical restraints: Restraint has proven efficacy in reducing injury and agitation.¹⁵⁶ If the patient continues to be uncooperative, rapidly gain control of the individual using several trained staff and physical restraints (Table 8.2.2 on restraining technique and Table 8.2.3 on universal precautions). Empty the room of all extraneous and/or potentially dangerous objects and apply the restraints in a humane and professional manner.¹⁵⁷ The method of restraint should be the least restrictive necessary for the protection of the patient and others.¹¹³

Secondary Interventions

1. Insert IV, monitor: Once the patient is restrained insert an intravenous line, and assess vital signs.

2. Assess underlying medical conditions: Draw blood and assess for serious medical conditions. Rule out metabolic disturbances (e.g., hypoxia, hypoglycemia, hyponatremia, thyrotoxicosis,

Table 8.2.2 Patient Management with Use of Restraints

-
- A. Rehearse strategies before employing these techniques.
 - B. Use restraints sooner rather than later and thoroughly document all actions.
 - C. Remember universal precautions (see Table 8.2.3).
 - D. Use restraints appropriately. The use of overwhelming force will often be all that is necessary to preclude a fight.
 1. When it is time to subdue the patient, approach him or her with at least five persons, each with a prearranged task.
 2. Grasp the clothing and the large joints to attempt to “sandwich” the patient between two mattresses.
 3. Place the patient on the stretcher face down to reduce leverage and to make it difficult for the patient to lash out.
 4. Remove the patient’s shoes or boots.
 5. In exceptional circumstances, as when the patient is biting, grasp the hair firmly.
 6. Avoid pressure to the chest, throat, or neck.
 - E. The specific type of restraint used (hands, cloth, leather, etc.) is determined by the amount of force needed to subdue (i.e., use hard restraints for PCP-induced psychoses).
 - F. Keep in mind, when using physical restraints, that the minimum amount of force necessary is the maximum that ethical practice allows. The goal is to restrain, not to injure. Restraining ties should be adequate but not painfully constricting when applied (being able to slip your finger underneath is a good standard). The restrained patient should be observed in a safe, quiet room away from the other patients; however, the patient must be reevaluated frequently, as the physical condition of restrained patients could deteriorate.
-

Table 8.2.3 Universal Precautions

-
1. Appropriate barrier precautions should be routinely used when contact with blood or other body fluids is anticipated. Wear gloves. Masks and eye protection are indicated if mucous membranes of the mouth, eyes, and nose may be exposed to drops of blood or other body fluids. Gowns should be worn if splashes of blood are likely.
 2. Hands and skin should be washed immediately if contaminated. Wash hands as soon as gloves are removed.
 3. Exercise care in handling all sharps during procedures, when cleaning them, and during disposal. Never recap or bend needles. Carefully dispose of sharps in specially designed containers.
 4. Use a bag-valve-mask to prevent the need for mouth-to-mouth resuscitation. Such devices should be readily available.
 5. Health care workers with weeping dermatitis should avoid direct patient care until the condition resolves.
 6. Because of the risk of perinatal HIV transmission, pregnant health care workers should strictly adhere to all universal precautions.
-

Note: In its 1987 recommendations, the Centers for Disease Control (CDC) stated that universal precautions “should be used in the care of all patients, especially including those in emergency-care settings in which the risk of blood exposure is increased and the infection status of the patient is usually unknown.” The CDC stipulated the six basic universal precautions above.

uremia), alcohol or sedative-hypnotic withdrawal, CNS infection (e.g., meningitis, encephalitis) or tumor, hyperthermia, postictal state, trauma, etc.

3. Frequent reassessment: Any patient left in physical restraints must have frequent reassessments of vital signs, neurological status, and physical examination.¹¹³ Sudden death, and asphyxiation, have occurred in individuals while in restraints.^{115,158–160}

4. Documentation: The patient’s danger to him- or herself, degree of agitation, specific threats, and verbal hostilities should all be documented in case of future charges by the patient that the patient was improperly restrained against his or her will (i.e., battery). Documentation should include the reasons for, and means of, restraint and the periodic assessment (minimum of every 20 min) of the restrained patient. Legal doctrines pertinent to involuntary treatment have been reviewed elsewhere.¹¹⁶

5. Medications: Sedation is necessary for patients struggling vigorously against restraints, or for patients who are persistently agitated, hyperthermic, panicking, or hyperadrenergic. Consider one of the following sedatives or combinations: See previous discussion under general comments.

Lorazepam	0.05–0.10 mg (2–7 mg) IM or IV initially over 1–2 min	May repeat doses every 5 min until sedation is achieved
Diazepam	to 0.20 mg/kg (5–10 mg) IV initially over 1–2 min	May repeat doses every 5 min until sedation is achieved Diazepam is not recommended in patients >60 years old due to prolonged duration of action in this group
Haloperidol	0.1–0.2 mg/kg (5–10 mg) IM or IV initially over 1–2 min	May repeat dosing 5 mg every 15 min until sedation is achieved Probably safe in most overdoses although more studies are necessary to confirm
Ziprasidone	10–20 mg IM	Studies still pending for use in patients with drug-induced agitation

6. Reassess medical condition: For persistently altered mental status perform CT of the head and consider lumbar puncture. Cases involving body packers^{161–163} or stuffers¹⁶⁴ with ongoing absorption of drug, or certain drugs that delayed absorption (i.e., belladonna alkaloids in Jimson weed¹⁶⁵) may have prolonged duration of symptoms.

7. Laboratory Data: Electrolytes, CBC, BUN, Cr, CPK, CPK with MB fraction if myocardial infarction or ischemia is suspected. Consider liver function studies including PT/ PTT in severely ill patients. Rule out coagulopathy with a disseminated intravascular coagulation (DIC) panel. Obtain blood and urine cultures if hyperthermic. While the use of toxicology screens of blood and urine are generally overutilized,⁵ they are recommended if the diagnosis remains questionable.

8. Disposition: Consider discharging patients who meet all the following criteria after an appropriate period of observation:

- a. Normal vital signs and mental status
- b. Normal or near normal laboratory data

Patients who have a chronically altered mental status, e.g., schizophrenia, or organic psychosis, and who are not at risk to themselves or others may be considered for discharge with appropriate psychological counseling and follow up. Patients with true delirium, or escalating agitation, or abnormal vital signs must be either admitted to the hospital or observed for further improvement.

8.2.3 Seizures

8.2.3.1 General Comments

Seizures from drug abuse have been known to be lethal^{166–168} or cause permanent neurological injury.^{169–171} Primate studies using baboons¹⁷² have shown that 82 min of induced status epilepticus produced visible neuropathological injury in nonparalyzed ventilated animals. Results were similar if the baboons were paralyzed and ventilated first. In addition to the potential for direct brain injury, prolonged seizure activity may cause or aggravate hyperthermia, which can further injury to the brain and produce rhabdomyolysis.

Mechanisms: Drugs may precipitate seizures through several distinct mechanisms (Table 8.2.4). A direct CNS stimulant effect is probably the mechanism in most cocaine-, phencyclidine-, and amphetamine-induced seizures.^{173,174} Seizures from these drugs generally occur *at the time of use* while seizures associated with other drugs such as alcohol, benzodiazepines, and barbiturates, generally occur during *a time of withdrawal* from chronic, high doses of the drug.¹⁷³ Other *indirect* causes of seizures exist. Cerebral infarction or hemorrhage may precipitate seizures in patients abusing cocaine or amphetamines.^{175,176} Vasculitis has been associated with amphetamine and cocaine abuse and may result in seizures.¹⁷⁷ Intravenous drug-abusing (IVDA) patients with acquired immune deficiency syndrome (AIDS) are susceptible to CNS infections such as toxoplasmosis, cryptococcus, viral encephalitis, and syphilis or lymphoma, which can precipitate seizures. IVDA also is frequently complicated by bacterial endocarditis, septic cerebral emboli, and seizures.

Table 8.2.4 Mechanisms of Drug-Related Seizures

-
1. Direct CNS toxicity: Cocaine, phencyclidine, amphetamines
 2. CNS hyperactivity after cessation of drug: Alcohol, barbiturates, benzodiazepines
 3. Indirect CNS toxicity
 - a. Trauma: subdural, epidural hematoma due to blunt force
 - b. Stroke: cerebral infarct, hemorrhage, or vasculitis
 - c. Infection of CNS
 - d. Foreign materials (e.g., talc), other drug adulterants (see Tables 8.2.5 to 8.2.7)
 - e. Systemic metabolic problems (e.g., hypoglycemia, liver, or renal failure)
 - f. Post-traumatic epilepsy, or epilepsy exacerbated by drug abuse
 - g. Epilepsy additional to drug use
-

Foreign material (e.g., talc or cotton) emboli and toxic drug by-products or expanders have been implicated¹⁷⁸ (Table 8.2.5 through Table 8.2.7) as well as brain trauma or closed head injury. Finally, chronic alcohol abuse often leads to systemic medical problems such as hypoglycemia, liver failure, sepsis, or meningitis, all of which may precipitate seizure activity.

Benzodiazepines: Benzodiazepines are the preferred choice for the initial control of the actively seizing patient.¹⁷⁹ Accordingly, pharmacological studies demonstrated that cocaine-induced seizures

were efficiently inhibited by GABA_A receptor agonists and NMDA receptor antagonists, whereas sodium and calcium channel blockers were ineffective.¹⁷⁴ Benzodiazepines, unlike MND A receptor antagonists, are readily available, require no prolonged loading, and are quite safe from a cardiovascular standpoint.^{180–182} The main disadvantages are excessive sedation and respiratory depression, especially when given with barbiturates such as phenobarbital. Lorazepam is also quite viscous and must be refrigerated and diluted before infusion.¹⁷⁹ Diazepam is irritating to veins and after intramuscular dosing absorption is unpredictable.

Which Benzodiazepine?: Of the benzodiazepines lorazepam has the longest anticonvulsant activity¹⁸³ (4 to 6 h) and is considered the agent of first choice. Lorazepam has a tendency to persist in the brain while agents like diazepam and midazolam both redistribute out of the brain more rapidly and thus have a shorter protective effect.¹⁸⁴ Leppik et al.¹⁸⁵ found no significant statistical difference between diazepam and lorazepam in clinical efficacy for initial control of convulsive status. It was found, however, that lorazepam provided seizure control in 78% of patients with the first intravenous dose while diazepam provided seizure control after the first injection only 58% of the time. Levy and Kroll¹⁸⁶ found that the average dose of lorazepam to control status epilepticus in a study of 21 patients was 4 mg and all patients responded within 15 min. Chiulli et al. reported on a retrospective study of 142 equally matched children given benzodiazepines and phenytoin for control of seizures.⁵³⁰ The intubation rate for those given lorazepam (mean dose 2.7 mg) was 27% while 73% of those given diazepam (mean dose 5.2 mg) had to be intubated. This study had an overall intubation rate that was quite high (45%), raising the question why so many children needed to be intubated.¹⁷⁹ Interestingly, lorazepam is not FDA-approved for seizure control. Midazolam may be used alternatively and has the advantage of rapid IM absorption in patients without venous access. In one study it was found to have a stronger influence on electroencephalographic measures,¹⁸⁷ and may be more effective in status epilepticus than diazepam or lorazepam.¹⁸⁸

Barbiturates: Barbiturates are associated with a higher incidence of hypotension than benzodiazepines,^{189–191} and as a result should not be administered in the hypotensive patient. Furthermore, they require time-consuming loading (greater than 30 min). Although phenobarbital may be administered at an IV rate of 100 mg/min (requiring only 10 min to fully load a 70-kg patient with 15 mg/kg) most nursing protocols require the physician to institute phenobarbital loading or to give no more than 60 mg/min IV.¹⁷⁹ Finally, barbiturates frequently cause prolonged sedation (especially after the co-administration of benzodiazepines) thus hindering the ability of the physician to perform serial examinations. Barbiturates do have an advantage of lowering intracranial pressure¹⁹⁰ in the head-injured patient and are helpful for treating withdrawal symptoms in patients with sedative-hypnotic addiction.^{192,193} Barbiturates (i.e., phenobarbital) are considered second-line agents after the use of benzodiazepines (i.e., lorazepam) for seizures caused by drugs of abuse.

Fosphenytoin: Phenytoin is a poorly soluble anticonvulsant that is mixed with propylene glycol to enhance its solubility. The propylene glycol, not the phenytoin, is a cardiac depressant and may cause hypotension and cardiovascular collapse if administered too rapidly. Fosphenytoin was recently introduced to eliminate the poor aqueous solubility and irritant properties of intravenous phenytoin and to eliminate the need for the propylene glycol solvent. Fosphenytoin is rapidly converted to phenytoin after intravenous or intramuscular administration and unlike phenytoin does not require prolonged administration of a loading dose on a cardiac monitor. In clinical studies, this prodrug showed minimal evidence of adverse events and no serious cardiovascular or respiratory adverse reactions.¹⁹⁴ Unlike phenobarbital and benzodiazepines, which elevate the seizure threshold, phenytoin exerts its anticonvulsant effects mainly by limiting the spread of seizure activity and reducing seizure propagation. Because phenytoin does not elevate the seizure threshold, it is less effective against drug-induced seizures.¹⁹⁵ Animal models¹⁹⁶ of cocaine-induced seizures and human studies¹⁹⁷ of alcohol withdrawal seizures have supported this claim. Cardiac toxicity of phenytoin was suggested by Callahan et al.¹⁹⁸ who showed an increased incidence of ventricular tachycardia in dogs intoxicated with amitriptyline treated with phenytoin. Fosphenytoin and phenytoin are thus

considered third-line agents for drug-induced seizures. They may be considered more useful for the drug-abusing patient with epilepsy whose seizures have responded to phenytoin in the past.

General anesthesia: Pentobarbital or thiopental anesthesia may be used as a last resort, usually with the aid of an anesthesiologist, to induce general anesthesia.^{199,200} If paralysis is used, the patient must be intubated and mechanically ventilated. It is important to remember that when patients having seizures are paralyzed with neuromuscular blockers such that seizure activity is not readily apparent, they may continue to have electrical seizure activity, which results in persistent cerebral hypermetabolism and the continued risk of brain injury.¹⁷² Munn and Farrell²⁰¹ reported on a 14-year-old girl who was pharmacologically paralyzed during 14 h of unrecognized status epilepticus. The originally healthy girl suffered persistent, serious cognitive impairment and subsequent epilepsy. An EEG should be used to monitor in all patients paralyzed for a seizure disorder to determine the need for further anticonvulsant therapy.

8.2.3.2 Stepwise Approach to Management

Immediate Interventions

1. Airway, Breathing, Circulation: Maintain the airway and assist ventilation if necessary. Administer supplemental oxygen. Treat hypotension, and resuscitate as per previous reviews.⁹⁰

2. Antidotes: Administer appropriate antidotes, including 25 g dextrose IV if the patient is hypoglycemic. Administer naloxone only if seizures are thought to be caused by hypoxia resulting from narcotic-associated respiratory depression.

3. Anticonvulsants: Administer one of the drugs listed in the tabulation below.

Comment: As noted above the authors have a strong preference for benzodiazepines (i.e., lorazepam). If lorazepam is chosen, most seizures stop after 2 to 4 mg, but there are no clear dose–response data available.¹⁷⁹ Some authorities stop if 4 mg is unsuccessful, but it seems reasonable to give up to 10 to 12 mg of lorazepam before switching to an alternative therapy. Neurologists generally recommend the aggressive use of a single drug before switching to another drug. Switching too quickly frequently results in the underdosing of both drugs. Respiratory depression should not keep one from using large doses of benzodiazepines¹⁷⁹ (as has been done safely with delirium tremens²⁰²), especially in the drug-abusing patient with status epilepticus. If large doses of benzodiazepines are used, patients frequently require intubation and mechanical ventilation.

Drugs Used for Seizure Control

Lorazepam	0.05–0.10 mg/kg IV over 2 min	May repeat as necessary, may give intramuscularly (IM) although IV route preferred
Midazolam	0.05 mg/kg IV over 2 min	May repeat as necessary
Diazepam	0.10 mg/kg IV over 2 min	May repeat as necessary
Phenobarbital	15–20 mg/kg IV over 20 min	Watch for hypotension, prolonged sedation
Fosphenytoin	15–20 mg/kg IV given at 100–150 mg/min (7–14 min)	Generally not as effective as benzodiazepines or barbiturates, may give IM although IV route preferred
Pentobarbital	5–6 mg/kg IV, slow infusion over 8–10 min, then continuous infusion at 0.5–3.0 mg/kg/h titrated to effect	Use as inducing agent for general anesthesia, watch for hypotension, continuous EEG monitoring necessary after general anesthesia

4. Reassess temperature: Immediately check the rectal temperature and cool the patient rapidly if the temperature is above 40°C (104°F) (see Section 8.2.4 on hyperthermia).

5. Lumbar puncture: Perform lumbar puncture if the patient is febrile to rule out meningitis. Do not wait for CT results or laboratory analysis of cerebral spinal fluid (CSF) to initiate therapy with appropriate antibiotics (i.e., a third-generation cephalosporin) if meningitis is suspected. Perform CT prior to lumbar puncture if the patient is at risk for having a CNS mass lesion.

Table 8.2.8 High-Risk Seizures

Neurological deficit
Evidence of head trauma
Prolonged postictal state
Focal seizures or focal onset with secondary generalization ^a
Seizures occurring after a period of prolonged abstinence ^a
Onset of seizures before age 30 if alcohol only involved
Mental illness or inability to fully evaluate the patient's baseline mental function

^a High risk for having a positive CT result requiring intervention.

6. Gastric decontamination: Consider gastrointestinal decontamination if the patient is a body packer or stuffer or if the patient has ingested large quantities of drug (see Section 8.2.9, gastric decontamination).

7. Laboratory Data: Electrolytes, glucose, calcium, magnesium, and biochemical screens for liver and renal disease are generally recommended.¹⁷³ Check creatine kinase levels to detect evidence of rhabdomyolysis. Although the use of urine and blood toxicologic screens are generally overutilized,⁵ they are recommended in the case of new onset seizures to avoid an inappropriate diagnosis of idiopathic epilepsy.

Secondary Interventions

1. Computerized Tomography (CT): Earnest et al.¹⁷⁸ documented a 16% incidence of “important intracranial lesions on CT scan” in a series of 259 patients with first alcohol-related seizures, and Pascual-Leone et al.²⁰³ found CT scan lesions in 16% ($n = 44$) of cocaine-induced seizures. Cocaine-induced thrombosis and hypertension have been implicated as the cause of stroke in patients with seizures.^{204–206} Considering these studies and also the high incidence of traumatic, hemorrhagic, and infectious injuries associated with drug abuse, a CT of the brain (with contrast) is recommended for new-onset seizures or for any high-risk seizures (Table 8.2.8). In a smaller study Holland et al.²⁰⁷ performed a retrospective review of 37 cocaine-associated seizures and concluded that CT scanning was not necessary regardless of the patient's previous seizure history if the patient suffered a brief, generalized, tonic–clonic seizure and had normal vital signs, physical examination, and a postictal state lasting 30 min or less. We await larger studies to confirm the Holland et al. findings prior to making similar recommendations.

2. Monitor: Monitor neurological and cardiovascular status as well as hydration and electrolyte balance.

3. Anticonvulsant therapy: Chronic anticonvulsant or other specific treatment of alcohol- or drug-related seizures rarely is indicated. For patients who present with multiple seizures, status epilepticus, or high-risk seizures (Table 8.2.8) continued outpatient therapy may be indicated.

4. Disposition: Only patients with normal vital signs, and physical examination; after a brief isolated seizure; with a normal evaluation (i.e., CT scan, laboratory data, etc.) should be considered for discharge from the emergency department.

8.2.4 Hyperthermia/Heat Stroke

8.2.4.1 General Comments

While mild hyperthermia is usually benign, in the setting of drug overdose it may be a sign of impending disaster. Severe hyperthermia ($>40.5^{\circ}\text{C}$) is a well-recognized cause of major morbidity and mortality, regardless of the cause. Classic heat stroke, for example, characterized by a core temperature of 40.5°C or higher, and severe CNS dysfunction has been associated with mortality rates of up to 80% as well as with a high likelihood of disabling neurologic sequelae.²⁰⁸ Although

no study has documented the incidence of death as it relates to drug abuse per se, a case series by Rosenberg et al.²⁰⁹ described 12 patients who presented with temperatures 40.5°C or greater for at least 1 h. Five of 12 patients died and four had severe permanent neurologic sequelae. Clinical signs common to patients who went on to develop severe hyperthermia were increased muscular activity and absence of sweating.

Classic vs. drug-induced heat stroke: If a patient with apparent environmental heat illness has a continuing rise in temperature even after removal from ambient heat and ongoing exertion, drug-induced hyperthermia must be strongly considered. Rosenberg et al. reported a 3 to 12 h delay to the onset of severe hyperthermia in 7 of 12 patients with drug-induced hyperthermia.²⁰⁹ A variety of drugs^{133,210–213} and toxins¹⁷¹ can cause hyperthermia, and this may initially be overlooked while the more familiar manifestations (i.e., seizures) of the intoxication are being managed. Patients with hyperthermia and altered mental status may be diagnosed as having environmental or exertional heat stroke while the potential contribution of drugs is neglected.²⁰⁹ Clues to drug-induced hyperthermia from the history and physical examination must be aggressively pursued.

Mechanisms: Mechanisms of drug-induced hyperthermia are varied. Most commonly, excessive heat production results from muscular hyperactivity (sympathomimetic and epileptogenic agents) or metabolic hyperactivity (salicylates). Heat dissipation is often impaired by inhibition of sweating (anticholinergic agents), cutaneous vasoconstriction (sympathomimetic agents), and/or by interference with central thermoregulation (phenothiazines, cocaine, amphetamines).^{209,214–216} When healthy, cocaine-naïve persons are subjected to passive heating, pretreatment with even a small dose of intranasal cocaine impairs sweating and cutaneous vasodilation (the major autonomic adjustments to thermal stress) and heat perception (the key trigger for behavioral adjustments).²¹⁷ The combined serotonin-releasing and dopamine-releasing drug MDMA produces lethal hyperthermia more potently than amphetamine,²¹⁸ supporting a synergistic role for serotonergic with dopamine in drug-induced hyperthermia.¹³³ *Phencyclidine* is a sympathetic nervous system stimulant, and may also have anticholinergic properties,²¹⁹ which inhibit sweating. This property plus the tendency to generate unrestrained outbursts of violent activity and seizures have resulted in hyperthermia and rhabdomyolysis and death.²²⁰ Of 1000 cases of PCP intoxication reviewed by McCarron et al.²²¹ 26 had temperatures over 38.9°C and four had temperatures over 41°C. Large overdoses of *LSD* have been associated with severe hyperthermia.^{222,223} This has been suggested to be due to its serotonergic effects²¹⁰ and a tendency to provoke panic. A patient restrained in a straitjacket after becoming violent after *LSD* ingestion developed hyperthermia to 41.6°C, hypotension, rhabdomyolysis, renal failure, and died.²²⁴ Specific mechanisms may dictate the specific form of hyperthermic syndrome although classically five syndromes are described: malignant hyperthermia, neuroleptic malignant syndrome, anticholinergic poisoning, sympathomimetic poisoning, and serotonin syndrome.

Malignant hyperthermia: Less commonly, drug-induced hyperthermia may develop as a form of malignant hyperthermia. Although hyperthermia associated with cocaine and PCP have been ascribed this diagnosis,^{225,226} malignant hyperthermia is a rare complication that is usually associated with exposure to volatile anesthetic agents or depolarizing muscle relaxants.¹⁷¹ The primary defect is felt to be an alteration in cellular permeability, which results in an inability to regulate calcium concentrations *within* the skeletal muscle fibers.²²⁷ As a result neuromuscular paralysis (acting at the *neuromuscular junction*) is not effective in controlling the severe muscular rigidity and heat generation seen with malignant hyperthermia. Dantrolene (1 to 2 mg/kg rapidly IV) is the most effective treatment for malignant hyperthermia. While dantrolene has been suggested to diminish hyperthermia associated with amphetamine^{228,229} and *LSD*²³⁰ overdose, it has not been shown in any controlled study to be effective and confirmation of its usefulness for these indications requires further evaluation.

Neuroleptic malignant syndrome: Neuroleptic malignant syndrome (NMS) is another uncommon cause of drug-induced hyperthermia associated with the use of haloperidol and certain other neuroleptic agents. It has been reviewed in depth elsewhere.^{212,231,232} Muscular rigidity, autonomic instability, and metabolic disturbances are presumed to occur due to neurotransmitter imbalances.

Neuromuscular paralysis and routine external cooling measures are generally effective for treatment of the severe rigidity and hyperthermia in this condition. In case reports NMS has been attributed to cocaine^{233,234} and LSD,²³⁰ although exertional hyperthermia seems a more probable diagnosis in these instances. Treatment includes the use of bromocriptine (5.0 mg per nasogastric tube every 6 h),²³⁵ and supportive care.

Serotonin syndrome: A clinical syndrome associated with increased free serotonin levels; usually the result of a prescription drug interaction such as selective serotonin-reuptake inhibitor with cocaine or amphetamines. Muscle rigidity is not as prominent as with NMS and sweating and gastrointestinal complaints are much more common. Symptoms of hyperthermia hyperreflexia, agitation, and an exaggerated tremor predominate.^{214–216}

Importance of paralysis and cooling: Zalis et al.^{236,237} showed that hyperthermia was directly related to mortality in mongrel dogs with *amphetamine* overdose. Paralysis was shown to stop muscle hyperactivity, reduce hyperthermia, and decrease mortality.²³⁸ Davis et al.²³⁹ showed that dogs treated with toxic doses of *PCP* exhibited toxicity, which was diminished by paralysis and cooling measures.²³⁹ Animal studies also indicate a key role for hyperthermia in complications associated with *cocaine* overdosage. Catravas and Waters¹²³ demonstrated that dogs given otherwise lethal *cocaine* infusions survived if severe hyperthermia was prevented. In this study temperature correlated better with survival than did pulse or blood pressure. Measures to prevent hyperthermia have included paralysis with pancuronium, sedation with chlorpromazine or diazepam, and external cooling.

Prognosis: Prognosis for severe hyperthermia depends on the *duration of temperature elevation*, the *maximum temperature* reached, and the affected individual's *underlying health*.²⁴⁰ *Coagulopathy* was reported to be associated with death in four of five cases in one report²⁰⁹ and has been shown to correlate with mortality in other studies.²⁴¹ *Seizures* are also associated with a poor prognosis.²⁰⁹ This may in part be because they are often resistant to treatment in the hyperthermic individual. Any *delay in cooling* has been associated with a significantly increased incidence of mortality as well.²⁴²

8.2.4.2 Stepwise Approach to Management

It does not take long either to boil an egg or to cook neurons.²⁴³

Immediate Interventions

1. Airway, Breathing, Circulation: Maintain the airway and assist ventilation if necessary. Administer supplemental oxygen. Treat hypotension, and resuscitate as per previous reviews.^{1–3}

2. Antidotes: Administer appropriate antidotes, including 25 g dextrose IV if the patient is hypoglycemic, as per the section on coma.

3. Control seizures and muscular hyperactivity: See Section 8.2.3, seizures, and Section 8.2.2, agitation.

4. Cooling: The fastest cooling techniques reported in the literature have usually been implemented in a research laboratory environment, utilizing animal models and equipment and techniques that are not universally available. In clinical practice, a technique that allows easy patient access and is readily available is preferable to a technique that may be more effective, but is difficult to perform. A comparison of the cooling rates achieved in several animal and human models with various cooling techniques is shown in Table 8.2.9. The advantages and disadvantages are summarized in Table 8.2.10. We favor evaporative cooling as the technique of choice. Evaporative cooling combines the advantages of simplicity and noninvasiveness with the most rapid cooling rates that can be achieved with any external techniques.²⁴⁴ Some authors advocate the use of strategically placed ice packs although there are no controlled studies demonstrating their effectiveness and ice packs may contribute to shivering, which may further increase heat generation. In the authors' experience with exercise-induced heat stroke, ice packs placed at the groin and axillae do not causing shivering if they were used when the temperature is high (>40°C) and removed as the

Table 8.2.9 Cooling Rates Achieved with Various Cooling Techniques

Technique	Author/Year	Species	Rate °C/min
Evaporative	Weiner/1980 ⁵²⁰	Human	0.31

Table 8.2.10 Various Cooling Techniques

Technique	Advantages	Disadvantages
Evaporative	Simple, readily available Noninvasive Easy monitoring and patient access Relatively more rapid	Constant moistening of skin surface required to maximize heat loss
Immersion	Noninvasive Relatively more rapid	Cumbersome Patient monitoring and access difficult — inability to defibrillate Shivering Poorly tolerated by conscious patients
Ice packing	Noninvasive Readily available	Shivering Poorly tolerated by conscious patients
Strategic ice packs	Noninvasive Readily available	Relatively slower Shivering
Cold gastric lavage	Can be combined with other techniques	Poorly tolerated by conscious patients
	Can be combined with other techniques	Relatively slower Invasive May require airway protection Human experience limited
Cold peritoneal lavage	Very rapid	Invasive Human experience limited

patient cools. Gastric lavage with cold water or saline is an effective and rapid central cooling technique that can be used in combination with evaporation in severe cases. Neuromuscular paralysis is recommended in all severe cases in which temperature is persistently greater than 40°C. Cooling technique is as follows:

- Completely remove *all* clothing.
- Place cardiac monitor leads on the patient's back so that they adhere to the skin during the cooling process.
- Wet the skin with lukewarm tap water with a sponge or spray bottle (plastic spray bottles work the best).

- d. Position *large high-speed fan(s)* close to the patient and turn them on.
- e. Place ice pack to the groin and axillae (optional).
- f. If shivering occurs, treat with diazepam, 0.1 to 0.2 mg/kg IV, or midazolam, 0.05 mg/kg IV.
- g. Treat continued muscular hyperactivity, i.e., either severe shivering, rigidity, or agitation, with neuromuscular paralysis (vecuronium, 0.1 mg/kg IVP) with endotracheal intubation and mechanical ventilation.
- h. Employ vigorous fluid replacement to correct volume depletion and to facilitate thermoregulation by sweating.
- i. If the patient continues to exhibit muscle rigidity despite administration of neuromuscular blockers, give dantrolene, 1 mg/kg rapid IV push. Repeat as necessary up to 10 mg/kg.
- j. Place a Foley catheter and monitor urine output closely.
- k. Monitor the rectal or esophageal temperature and discontinue cooling when the temperature reaches 38.5°C to avoid hypothermia.

Comments:

Immersion: Immersion in an ice water bath is also a highly effective measure to reduce core temperatures, but limits the health care provider's access to the patient, and requires more equipment and preparation.

Thermometry: Unfortunately, most standard measurements of body temperature differ substantially from actual core temperature. Oral thermometry is affected by mouth breathing and is a poor approximation of core temperature. Rectal thermometry is less variable, but responds to changes in core temperature slowly. Thermistors that are inserted 15 cm into the rectum offer continuous monitoring of temperature with less variability and, although slower to respond to changes in core temperature than tympanic temperature readings, are not biased by head skin temperature. Temperatures taken using infrared thermometers that scan the tympanic membrane are of variable reliability and reproducibility.^{245–248} Studies have shown that infrared tympanic membrane thermometers may be influenced by patient age,²⁴⁹ measuring technique,²⁵⁰ the presence or absence of cerumen,^{245,251} and head skin temperature as noted above.²⁵² If a patient has a Swan-Ganz catheter, pulmonary arterial temperature may be measured precisely with a thermistor catheter. An esophageal thermistor positioned adjacent to the heart closely correlates with core temperature as well. It is the least invasive, most accurate method available in the emergency department and is recommended (although rectal thermistors will suffice for most cases). Thermistors attached to urinary catheters may work equally well.

Circulatory support: Usually, fluid requirements are modest, averaging 1200 ml of Ringer's lactate or saline solution in the first 4 h.^{253,254} This is because a major factor in the hypotensive state is peripheral vasodilation.¹⁷¹ With cooling there may be a sudden rise in systemic vascular resistance, and pulmonary edema may be caused, or exacerbated, by overzealous fluid administration.^{255,256} Insertion of a Swan-Ganz catheter or central venous pressure monitor is indicated whenever necessary to guide fluid therapy. Patients with low cardiac output and hypotension should not be treated with α -adrenergic agents since these drugs promote vasoconstriction without improving cardiac output or perfusion, decrease cutaneous heat exchange, and perhaps enhance ischemic renal and hepatic damage.²⁵⁷ One case report described excellent results using low-dose continuous isoproterenol infusion (1 μ g/min).²⁵³

Shivering: Since shivering may occur with rapid cooling, and thus generate more heat, some authors^{257,258} recommend chlorpromazine as an adjunct measure. Chlorpromazine is felt to act as a muscle relaxant and vasodilator promoting heat exchange at the skin surface. Phenothiazines, however, may aggravate hypotension, and have anticholinergic properties. They are also associated with serious dystonic reactions that may exacerbate hyperthermia. Distinct subtypes of dopamine receptors have been identified, including D_1 and D_2 receptors. Chlorpromazine and haloperidol are D_2 receptor antagonists and rat studies have shown that specific D_1 receptor antagonist, but not D_2 receptor antagonists reduced the hyperthermic response to cocaine infusion.²⁵⁹ Dopamine is also known to participate in core temperature regulation, but it is unclear whether a predominance of D_1 or D_2 receptor activation results in hyperthermia or hypothermia.²⁶⁰ Until more is understood about the exact role of the dopaminergic system in hyperthermia, the use of chlorpromazine and other dopamine blockers in the management of hyperthermia victims is not recommended.

Other pharmacologic interventions: Pharmacologic interventions aimed specifically at hyperthermia (i.e., dantrolene) have been suggested for such drugs as MDMA (i.e., ecstasy)²²⁸ but have not been proven to be of any benefit.^{229,261} Antipyretics are of no specific benefit²⁶² and salicylates may aggravate bleeding tendencies.²⁶³ Alcohol sponge baths are not recommended, particularly in small children, since alcohol may be absorbed through dilated cutaneous blood vessels and inhaled, producing isopropanol poisoning and coma.²⁶⁴

Secondary Interventions

1. Laboratory Data: Send blood for complete blood count, platelet count, PT, PTT, electrolytes, calcium, CPK, cardiac enzymes, BUN, creatinine, and liver function tests. Type and cross-match blood and send blood cultures. For severely ill patients send lactic acid level, and ABG. Check serum CPK and urine for myoglobin. If rhabdomyolysis is suspected, see Section 8.2.5 on rhabdomyolysis. Although urine and blood toxicologic screens are generally overutilized,⁵ they should be sent if the diagnosis is in question. Send salicylate levels on all cases with an unknown cause of hyperthermia.

2. CT: Consider CT of brain for persistently altered mental status, focal neurological deficit.

3. Lumbar puncture: Perform lumbar puncture and send cerebral spinal fluid for analysis if patient has signs or symptoms of meningitis. Do not wait for results before administering empiric antibiotics.

4. Cardiac evaluation: ECG, CXR.

5. Disposition: All patients with serious hyperthermia or heat stroke should be admitted to the hospital. Patients with normal or mildly abnormal laboratory values who become normothermic in the emergency department may be admitted to the medical floor. All others require intensive monitoring.

8.2.5 Rhabdomyolysis

8.2.5.1 General Comments

Rhabdomyolysis is defined as a syndrome of skeletal muscle injury or necrosis with release of muscle cell contents into the blood.²⁶⁵ It has been associated with all drugs of abuse.^{133,224,266–277} Since the classic signs and symptoms of nausea, vomiting, myalgias, muscle swelling, tenderness, and weakness are present in only a minority of cases (13% in one study²⁷⁸), the diagnosis depends on laboratory evaluation and a high clinical suspicion. Elevated levels of serum CK, in the absence of CK from other sources (brain or heart), is the most sensitive indicator of muscle injury²⁶⁵ with most authors recognizing a CK level of more than fivefold that of the upper limit of normal as diagnostic. The diagnosis may also be suspected with a positive urine dipstick for heme; if no red blood cells are present on the urine microscopic examination, the positive orthotolidine reaction may be attributed to myoglobin (or hemoglobin). Because myoglobin is cleared from the plasma in 1 to 6 h by renal excretion and by metabolism to bilirubin,²⁶⁵ the urine dipstick test for myoglobin may occasionally be negative due to rapid clearance.^{279,280} Gabow et al.²⁶⁵ reported that in the absence of hematuria, only 50% of patients with rhabdomyolysis had urine that was orthotolidine-positive.

The diagnosis of rhabdomyolysis is important because it may produce life-threatening hyperkalemia and myoglobinuric renal failure; it is often associated with disseminated intravascular coagulation (DIC), and acute cardiomyopathy from serious underlying conditions such as heat stroke or severe acidosis.^{265,277,280–282} Myoglobinuric renal failure may frequently be prevented by vigorous treatment.

Case in point: In 1984, Ron and colleagues²⁸³ described seven patients at very high risk for developing renal failure as a result of extensive crush injuries, severe rhabdomyolysis, and gross

myoglobinurea following the collapse of a building. Their treatment goal was to rapidly obtain a urine pH of 6.5 and to maintain diuresis of 300 ml/h or more. Crystalloid infusions were begun at the scene and continued during transport to the hospital. If urine output did not rise to 300 ml/h and the central venous pressure rose by more than 4 cm H₂O, the infusion was halted and 1 g mannitol/kg body weight as a 20% solution was administered IV. Sodium bicarbonate (44 mEq) was added to every other bottle of 500-ml crystalloid solution. The electrolyte composition of IV solutions was adjusted to maintain a serum sodium concentration of 135 to 145 mmol/L and a serum potassium concentration between 3.5 and 4.5 mmol/L. Repeated doses of mannitol (1 g/kg body wt) were given if the urine output fell below 300 ml/h for 2 consecutive hours and if the central venous pressure rose by more than 4 cm H₂O. Further doses of bicarbonate were given if the urine pH fell below 6.5. Acetazolamide was given intravenously if plasma pH approached 7.45. Despite peak creatinine kinase (CK) levels exceeding 30,000 IU/dl none of the seven patients developed renal failure.

Assessing risk for developing acute renal failure: Several heterogeneous studies have attempted to identify which patients will progress to myoglobinuric renal failure based on their laboratory values. Unfortunately, there are no prospective studies with standardized treatment regimens to determine which patients are at risk. A study of 200 victims of severe beatings in South Africa found that base deficit, delay in treatment, and CK levels were significant risk factors for the development of ARD and death.²⁸⁴ Ward et al.,^{284a} in another retrospective study ($n = 157$) found that the factors predictive of renal failure included (1) a peak CK level greater than 16,000 IU/dl (58% of patients with CK above 16,000 IU/dl vs. 11% of patients with CK below 16,000 IU/dl developed renal failure), (2) a history of hypotension, (3) *dehydration*, (4) older age, (5) sepsis, and (6) hyperkalemia. A retrospective review of 93 patients with “severe” rhabdomyolysis (serum CK greater than 5000 U/L) found that patients with a peak CK level of greater than 15,000 U/L had significantly higher rates of acute renal dysfunction (72% vs. 38%).²⁸⁵ A recent analysis of 372 patients with crush syndrome after the 1995 earthquake in Kobe, Japan, demonstrated that patients with a peak CK level greater than 75,000 U/L had a higher rate of acute renal failure and mortality than those with a peak CK less than 75,000 U/L (84% vs. 39% and 4% vs. 17%, respectively).²⁸⁶ Eneas et al.²⁸⁷ found that only patients with a peak CK greater than 20,000 U/L failed to respond to a mannitol–bicarbonate diuresis and went on to require dialysis. The nonresponders also had significantly higher serum phosphate levels and hematocrit readings upon admission, indicative of more severe muscle injury and hemoconcentration. Several studies have attempted to predict the development of renal failure using serum or urine myoglobin levels. A prospective study of eight patients by Feinfeld²⁸⁸ found that four of five patients with urine myoglobin levels greater than 1000 ng/ml (normal = <10 ng/ml) developed acute renal dysfunction, while none of the three patients with urine myoglobin levels less than 300 ng/ml developed it. Another report found that elevated urine myoglobin levels greater than 20,000 ng/ml were associated with a significantly increased risk of renal dysfunction.²⁸⁹

Prognosis: Approximately 10% of patients with rhabdomyolysis presenting to hospitals develop myoglobinuric renal failure²⁷⁷ and major reports of patient series indicate that approximately 5% of patients with serious rhabdomyolysis die.^{265,268,280,281,290} Death is often due not to rhabdomyolysis or one of its complications but to a complication of the primary disorder associated with the rhabdomyolysis (i.e., traumatic injury, or sepsis). With temporary support from hemodialysis acute myoglobinuric renal failure has a good prognosis, and full recovery should be expected.^{280,281,291}

Crystalloids: Less controversy exists behind the need for volume replacement in the setting of rhabdomyolysis than it does for the use of bicarbonate, mannitol, or furosemide. In reviews of myoglobinuric renal failure,^{265,268,280,283,292–295} hypovolemia is a consistent finding among all evaluated risk factors. Myoglobinuric renal failure seen in military recruits and bodybuilders has an especially strong association with dehydration.^{296–298} Recently, Zurovsky et al.²⁹⁹ demonstrated that, in rats, mortality and renal failure increased from both chronic dehydration (24 to 72 h) and acute dehydration from sucrose-induced diuresis or hemorrhage. The role of dehydration appears to

implicate renal ischemia and perhaps acidosis and/or aciduria as necessary cofactors in the development of myoglobinuric acute renal failure.³⁰⁰

Alkalinization: The purpose of alkalinization of urine is to prevent the dissociation of myoglobin into globin and heme. Dissociation has been shown to occur below a pH of 5.6.³⁰¹ The nephrotoxic effect of heme has been ascribed to the production of free hydroxy radicals.³⁰² Dog studies have shown that the infusion of free heme causes significantly greater renal dysfunction than does myoglobin.³⁰³ Furthermore, in urine below pH 5.0, the solubility of myoglobin decreases markedly causing myoglobin cast formation and an increase in the percentage of myoglobin retained in renal tubules. This process has been shown to have a high correlation with the development of acute renal failure.³⁰⁴ Rabbit studies by Perri et al.³⁰⁵ showed that animals with a urinary pH of less than 6 invariably develop renal failure after infusions of myoglobin, whereas those with a urine pH of more than 6 do not develop renal insufficiency. Despite well-performed animal studies, no controlled human studies have evaluated the effectiveness of alkalinization for rhabdomyolysis. For this reason, as well as certain concerns about hypernatremia, hypervolemia, and hypocalcemia, some authors³⁰⁶ do not recommend bicarbonate therapy. We feel that the preponderance of evidence favors the use of bicarbonate and that with adequate monitoring of volume, electrolyte, and calcium levels bicarbonate therapy is safe and likely to be of benefit.

Mannitol: Three major mechanisms have been proposed to explain the protective action of mannitol. The first suggests that a diuresis may simply dilute nephrotoxic agents in urine (e.g., heme, urate) and “flush out” partially obstructed tubules.³⁰⁷ Knochel points out that renal tubular oxygen consumption is closely coupled to sodium reabsorption²⁸² and by preventing sodium reabsorption, mannitol or furosemide may decrease oxygen requirements of renal tubules. This may allow the tubules to survive the metabolic insult produced by heme.²⁷⁷ Finally, mannitol may simply convert oliguric renal failure to non-oliguric renal failure. Studies have demonstrated a lower morbidity and mortality in nonoliguric renal failure than in oliguric renal failure.^{308,309} Wilson et al.³¹⁰ showed that mannitol plus saline almost totally prevented the development of azotemia after glycerol-induced rhabdomyolysis in rats. As with bicarbonate, mannitol has not been shown to be more effective in prospective, controlled trials than saline alone. In selected cases in which urinary output is low (see following recommendations) and where hemodynamic status is stable, we believe potential benefits of mannitol administration outweigh the potential risks.

Furosemide: Loop diuretics such as furosemide have also been used in an attempt to prevent acute renal failure. As with mannitol and bicarbonate no controlled human studies on its efficacy have been done. Furosemide may work similarly to mannitol to decrease sodium reabsorption and thus conserve renal tubule energy expenditure, thus decreasing the risk of ischemia. It may also simply convert oliguric renal failure to non-oliguric renal failure. Furosemide has the advantage of not increasing serum osmolality to the extent that mannitol does, but may exacerbate hypovolemia if not used with caution.

Recommendation: Based on the report by Ron and co-workers,²⁸³ animal studies, and personal experience with the treatment of more than 100 cases of documented rhabdomyolysis, Curry et al.²⁷⁷ proposed a treatment regimen that we recommend with adjustments under a stepwise approach to management. Using this treatment approach Curry et al. report only two instances of myoglobinuric renal failure out of 100 patients presenting with evidence of rhabdomyolysis. One was in a woman with severe salicylate poisoning who had established renal failure and anuria at the time of admission. The second was a woman who had sepsis and anoxic encephalopathy after seizures and cardiac arrest from IV cocaine.²⁷⁷ While this regimen has not been tested prospectively it has suggestive benefit and if volume, serum osmolality, and electrolyte status are monitored it is quite safe. Patients lacking nephrotoxic risk factors such as dehydration and acidosis, with only mild elevations of CK (<16,000 IU/dl) and no ongoing muscle injury may not require the full course of therapy recommended here. Any patient not treated by the full protocol should have CK levels monitored closely (i.e., every 12 h) and should be able to drink large amounts of fluids to maintain a brisk *urine output*.

8.2.5.2 Stepwise Approach to Management

Immediate Interventions

1. Airway, Breathing, Circulation, Antidotes: Maintain the airway and assist ventilation if necessary. Administer supplemental oxygen. Treat hypotension, and resuscitate as per previous reviews.³ Administer appropriate antidotes, including 25 g dextrose IV if the patient is hypoglycemic, as per the section on coma.

2. Crystalloid: If cardiac/volume status is stable, initiate a fluid bolus of 1 L normal saline and continue until hypovolemia is corrected. Assuming that larger volumes are not needed for other reasons, crystalloid infusion is then administered at a rate of 2.5 ml/kg body weight per hour. Monitor urine output closely.

3. Bicarbonate: If urinary pH is <5.6 (the pH at which myoglobin dissociates into globin and heme), administer sodium bicarbonate IV in boluses of 1 mmol/kg body weight until the arterial blood pH is about 7.45 or the urinary pH rises to 5.6.

Comment: Urinary pH, not arterial pH, has been found to correlate with precipitation of myoglobin within renal tubules,^{304,305} and as a result the primary concern should be to increase urinary pH. Because of metabolic complications that may exist at a higher arterial pH (hypokalemia, and the shifting of the oxygen-hemoglobin saturation curve to the left), bicarbonate should not be used if serum pH is already >7.45.

Secondary Interventions

1. Reassess: Check serum sodium and potassium concentrations, and urine pH frequently.

Comment: If large volumes of normal saline are required for resuscitation, or sodium bicarbonate is used, check sodium every 6 to 8 h; otherwise check every 12 to 24 h. Check arterial pH every few hours if the patient is significantly acidotic (pH < 7.3) or if large amounts of sodium bicarbonate are used.

2. Potassium: Potassium may help to maintain a more alkaline urine. If urine pH falls below 5.6 in the presence of alkalemia and serum potassium is less than 4.0 mEq/L, then administer additional potassium until the urine pH rises above 6.0 or until the serum potassium concentration reaches 5 mmol/L.

Comment: The kidney of patients with hypokalemia will spare potassium and excrete hydrogen ions resulting in a decrease of urinary bicarbonate, thus maintaining aciduria. Acidic urine increases myoglobin precipitation and increases the risk of myoglobinuric renal failure. There are no controlled studies demonstrating the role of potassium in the treatment of rhabdomyolysis, but it is of little harm and may be beneficial. One study showed that during active work, potassium may act as a vasodilator and increase blood flow to working muscle.³¹¹ Knochel et al.³¹² have presented data demonstrating that skeletal muscle of potassium-depleted dogs releases very little potassium during exertion and that exertion is not accompanied by an increase in blood flow. This may result in localized muscle ischemia and persistent rhabdomyolysis.

3. Acetazolamide: Acetazolamide, like potassium, may assist in producing a more alkaline urine. If the patient is persistently aciduric despite alkalemia and normal serum potassium concentrations, Curry et al.²⁷⁷ recommend the use of 250 mg of acetazolamide IV to increase urinary pH. There is, however, no evidence that acetazolamide is efficacious for treatment of rhabdomyolysis.

Comment: In general, acetazolamide should not be given to a patient suffering from salicylate poisoning since it acidifies blood and alkalinizes CSF, increasing the volume of distribution of salicylate and trapping salicylate in the CNS.^{313–315} In animal models of salicylate poisoning, the administration of acetazolamide markedly increases mortality rate.³¹⁵

4. Decreased urine output below 1.5 to 2.0 ml/kg/h with objective hemodynamic parameters of either normovolemia or hypovolemia: Administer more crystalloid (500 cc fluid bolus) and consider increasing crystalloid infusion rate to 3.5 cc/kg/h.

5. Decreased urine output below 1.5 to 2.0 ml/kg/h with objective hemodynamic parameters of hypervolemia (Mannitol): Give a single dose of 1 g/kg body weight IV over 30 min, administer any additional doses 0.5 g/kg IV over 15 min. Monitor serum osmolality if repeated doses are required. Mannitol may be administered every 6 h if serum osmolality remains below 300 mOsm/L.

Comment: Watch for pulmonary edema and monitor serum osmolality. Mannitol should also not be used in the presence of hemorrhagic shock or hypovolemia.

6. Furosemide: If urine output does not respond to fluids or mannitol, then administer furosemide. Start with 10 mg IVP.

7. Discontinuation of therapy: Continue the above treatment protocol until the urine is consistently orthotolidine-negative, laboratory signs of continued rhabdomyolysis are no longer present, and renal function is improving or normal. Stop fluids, mannitol, and bicarbonate if oliguria or anuria are refractory to therapy.

8. Hemodialysis: Those who do go on to develop acute tubular necrosis may require hemodialysis or peritoneal dialyses for several days or weeks until renal function returns.^{265,277,280,281} Indications for hemodialysis include serious electrolyte abnormalities (e.g., hyperkalemia), clinically significant acidosis resistant to conventional therapy, and volume overload. A moderate elevation of BUN and creatinine levels without other clinical effects is not an indication for dialysis.³⁰⁶

9. Hyperkalemia: Sodium bicarbonate, glucose and insulin, sodium polystyrene, calcium, and dialysis may be required in severe cases.^{265,281}

10. Hypocalcemia: Hypocalcemia is common in patients with severe rhabdomyolysis²⁷⁷ but even with calcium levels less than 8.0 mEq/L, hypocalcemia rarely causes symptoms.^{282,316,317} Treatment of asymptomatic hypocalcemia has been discouraged because it theoretically could increase deposition of calcium due to precipitation with phosphate in damaged muscle, further augmenting rhabdomyolysis.³¹⁶

11. Laboratory Data: CBC, electrolytes, BUN, creatinine, calcium, phosphorus, urinalysis, urine dip for blood (orthotolidine test), CK (MM and MB fractions), and arterial blood gas (if sodium bicarbonate to be used) (Figure 8.2.1).

12. Disposition: Patients with drug overdose who present with mild elevations of their CK (less than 3000 U/L) may be considered for discharge if all of the following conditions are met:

- a. The patient must have normal vital signs.
- b. There is no evidence of ongoing muscle injury.
- c. The patient has normal renal function.
- d. The patient is well hydrated and not acidotic, with normal electrolytes.
- e. The patient can take fluids by mouth and is not at risk for dehydration.
- f. Follow up is easily arranged for repeat CK in 12 to 24 h.
- g. A repeat serum CK level 6 to 8 h after the first shows a decreasing trend.

All other patients should be admitted to the hospital for aggressive fluid therapy as described above.

8.2.6 Hypertensive Emergencies

8.2.6.1 General Comments

Hypertension: Drug-induced hypertension is of concern because it can cause stroke (usually cerebral hemorrhage), acute myocardial infarction, pulmonary edema, dissecting aneurysm, and/or hypertensive encephalopathy.^{319–321} Phenylpropanolamine, in particular, has been associated with

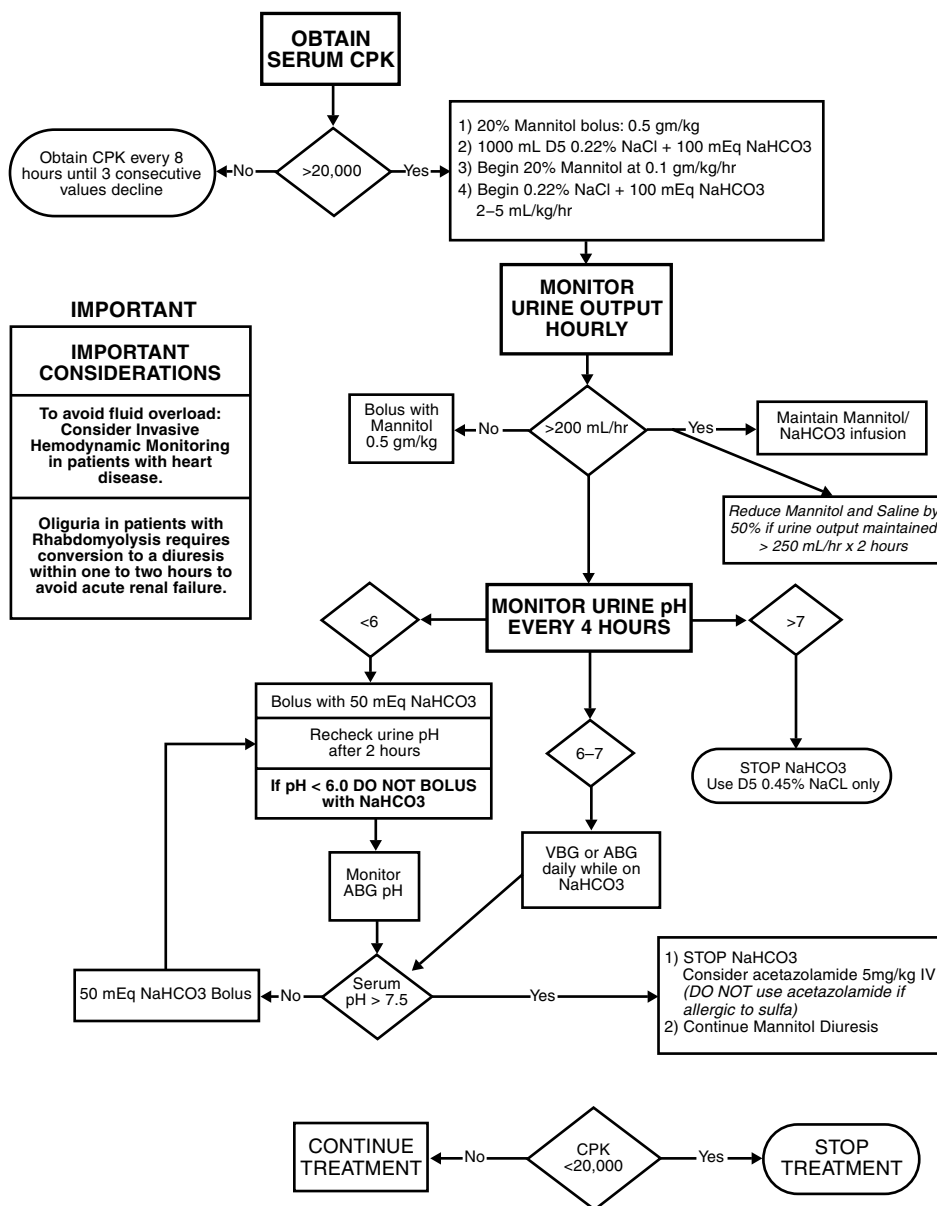

Figure 8.2.1 Treatment algorithm by Malinoski et al.,³¹⁸ which is a slightly more aggressive alternative to the protocol recommended above, advocating the use of mannitol and sodium bicarbonate in all patients.

cerebral hemorrhage when blood pressure was not rapidly lowered.^{322–324} In patients with hypertension associated with amphetamines or cocaine, benzodiazepines may be successful in controlling the hypertension (and possibly dysrhythmias) by reducing the central sympathetic stimulus^{123–125} and related catecholamine release.^{325,326} If a stable, previously normotensive patient, without evidence of end organ damage, has extremely high blood pressure (>120 mm Hg diastolic) despite sedation, one should consider the use of a vasodilator such as nitroglycerin or phentolamine, or possibly a calcium channel blocker.³²⁷ In contrast to patients with chronic hypertension, most young patients with drug-induced hypertension do not have chronic compensatory changes in their cerebral

and cardiovascular system. For this reason blood pressure in previously normotensive individuals may be reduced rapidly to normal levels.³²⁸

Hypertensive emergencies: Hypertensive emergencies, defined as an increase in blood pressure that causes functional disturbances of the CNS, the heart, or the kidneys,³²⁹ require a more aggressive approach.^{330–332} Evidence of hypertensive encephalopathy, acute heart failure, aortic dissection, or coronary insufficiency requires rapid reduction of blood pressure (usually within 60 min) in a controlled fashion. Direct arteriolar dilating agents such as nitroglycerin, or nitroprusside, a pure alpha-adrenergic blocking agent such as phentolamine, or a calcium antagonist³³³ may be used.

Stroke: Hypertension in the presence of a stroke is a more complicated issue, since hypertension may be a homeostatic response to maintain intracerebral blood flow in the presence of intracranial hypertension.³³⁴ In this case blood pressure should not be lowered, or, if there is ongoing evidence of sympathomimetic drug intoxication, lowered gradually to a diastolic blood pressure no less than the 100 to 110 mm Hg range.

Beta-blockers: In animal models of cocaine intoxication associated with hemodynamic dysfunction and mortality, propranolol has been shown to be protective,³³⁵ to have no effect,³³⁶ or to increase mortality.^{337,338} The reasons for the differences in these experimental results are unclear but may be related to the different doses of cocaine or the type of beta-adrenergic antagonist utilized.³³⁹ Human studies, however, have been more consistent. In a randomized, double-blinded, placebo-controlled trial, Lange et al.³⁴⁰ administered intranasal cocaine to 30 stable volunteers referred for cardiac catheterization. In this study it was found that intracoronary propranolol administration caused no change in arterial blood pressure but decreased coronary sinus blood flow and increased coronary vascular resistance. Several case reports have also documented an aggravation of hypertension when nonselective beta-adrenergic antagonists have been used in the treatment of acute cocaine intoxication.^{341–343}

Labetalol: The exacerbation of hypertension and coronary vasospasm when nonselective beta-adrenergic antagonists are administered to cocaine-intoxicated patients may result from blockade of beta-2 receptor-induced vasodilation causing an “unopposed” peripheral alpha-adrenergic vasoconstriction.³³⁹ It has therefore been suggested that labetalol, which has both alpha-adrenergic and beta-adrenergic antagonist activity, may be safer.^{154,342} Controversy exists since the beta-adrenergic antagonist potency of labetalol is seven times greater than its relatively weak alpha antagonist potency,³⁴⁴ and studies of hypertension in cocaine-intoxicated animals are conflicting: some have shown hemodynamic improvement³⁴⁵ while others show no hemodynamic effect.³⁴⁶ Mortality data are difficult to decipher as studies have shown decreased mortality,³³⁵ increased mortality,^{337,338} or no change in mortality.³³⁶ The human experience (case reports) with labetalol has been better than with propranolol,^{342,347,348} but in two unusual cases involving catecholamine excess that physiologically resemble cocaine intoxication (one involving pheochromocytoma,³⁴⁹ and the other an accidental epinephrine overdose³⁵⁰), hypertension was exacerbated by the administration of labetalol. In a study similar to that of Lange et al.,³⁵¹ Boehrer et al.³⁵² evaluated 15 patients referred for cardiac catheterization and found that while labetalol reversed the cocaine-induced rise in mean arterial pressure *it did not* alleviate cocaine-induced coronary vasoconstriction. An interesting case report described the induction of life-threatening hyperkalemia in a dialysis patient with hypertensive emergency treated with labetalol.³⁵³

Esmolol: Esmolol, an ultra-short acting ($t_{1/2} = 9$ min), easily titrated, beta-1 selective, adreno-receptor blocking agent, has been used successfully in the treatment of cocaine-induced adrenergic crises.^{126,343,354} However, the effects of esmolol on coronary vasoconstriction have not been evaluated. Its use may be most appropriate to control heart rate in the setting of acute aortic dissection³⁵⁵ induced by hypertension from stimulant abuse. If esmolol is used, it is recommended that vasodilators such as nitroglycerin be given simultaneously since nitroglycerin is known to alleviate stimulant-induced vasoconstriction.³⁵⁶ Pollan et al.³⁵⁴ reported a case of a 64-year-old man who became hypertensive and tachycardic after the administration of cocaine for nasal polyp removal. This patient had *resolution* of ST segment depression after the administration of 20 mg IV of

esmolol with good control of hemodynamic parameters. Esmolol has also been used in the management of pheochromocytoma with a rapid decrease in systolic blood pressure without effect on diastolic pressure.^{357,358}

8.2.6.2 Stepwise Approach to Management

Immediate Interventions

1. Airway, Breathing, Circulation: Maintain the airway and assist ventilation if necessary. Administer supplemental oxygen. Resuscitate as per previous reviews.³

2. Antidotes: Administer appropriate antidotes, including 25 g dextrose IV if the patient is hypoglycemic, as per Section 8.2.1.

3. Agitation or Seizures: Administer a benzodiazepine such as lorazepam (0.05 to 0.10 mg/kg) and control agitation as described under Section 8.2.2.

4. Medications: If the patient is persistently hypertensive and a hypertensive emergency exists, then administer one of the following drugs:

Treatment for Drug-Induced, Hypertensive Emergency

Drug	Dose	Onset	Mechanism of Action
Sodium nitroprusside	0.25–10 µg/kg/min as IV infusion	2–5 min	Direct arterial and venous vasodilator
Nitroglycerin	5–100 µg as IV infusion	2–5 min	Direct arterial and venous vasodilator
Esmolol	Load with 500 µg/kg/min over 1 min Maintenance infusion: 50–200 µg/kg/min	2–5 min	B ₁ adrenoreceptor blocker
Phentolamine	5–10 mg IVP	2–5 min	Alpha-adrenergic blocker

The treatment goal is to lower the blood pressure to a level that is “normal” for that patient within 30 to 60 min in a controlled, graded manner.³²⁹ Although there is a broad range of normal blood pressures for an individual, if the patient’s normal blood pressure is unknown, the diastolic blood pressure should be lowered to a minimum of 120 mm Hg or until there is no evidence of ongoing organ injury. The use of nitroprusside generally requires continuous intra-arterial blood pressure monitoring.

Comment: Phenylpropanolamine, an indirect sympathomimetic and direct alpha agonist, is frequently substituted for stimulants such as amphetamine and cocaine. The combination of severe hypertension with reflex bradycardia is a clue to vasoconstriction from the direct alpha-stimulation from phenylpropanolamine. Hypertension from phenylpropanolamine is usually best treated with phentolamine.

5. Laboratory data/imaging: For patients with hypertensive emergencies: Draw electrolytes, CK, CK-MB, BUN, creatinine, and PT/PTT. Perform EKG, and CXR. For apparently uncomplicated hypertension: Laboratory data may be done at the discretion of the physician. An ECG is recommended to rule out silent ischemia.

Secondary Interventions

1. Monitoring: Continue close monitoring of patient’s blood pressure and cardiac status with frequent manual blood pressure readings. Consider placing an arterial line for better monitoring in patients with persistently labile hypertension or for those who have hypertension that is difficult to control.

2. CT of brain: Patients with severe headaches that do not resolve after the control of hypertension should undergo CT of the head to rule out intracranial bleeding.

3. Lumbar puncture: If CT of head is negative and the patient continues to have symptoms of severe headache and/or nuchal rigidity, perform lumbar puncture to rule out small subarachnoid hemorrhage.

4. Disposition: All patients that meet the following conditions may be considered for discharge from the emergency department:

- a. Moderate uncomplicated hypertension controlled with sedation or a single dose of antihypertensive agents
- b. Normal vital signs after a period of observation of 4 to 6 h
- c. Normal ECG
- d. Normal physical examination

All patients with hypertensive emergencies should be admitted to the hospital regardless of response to initial therapy.

8.2.7 Cardiac Care

8.2.7.1 General Comments

Almost all drugs of abuse can be associated with acute cardiac complications ranging from benign supraventricular tachycardia to ventricular fibrillation, sudden death, and myocardial infarction. Cocaine is a prototype cardiac toxin among drugs of abuse. As such, most of this section pertains directly to cocaine. Other stimulants (i.e., amphetamines,^{359,360} phenylpropanolamine,^{361,362} and methylphenidate^{363,364}) may be associated with cardiac complications as well, and management should proceed in a fashion similar to that of the cocaine-intoxicated patient. One should also consider the likely possibility that cocaine has been mixed with or substituted for other stimulants (see Table 8.2.5 to Table 8.2.7).³⁶⁵ If cardiac complications occur from drugs of abuse other than stimulants (i.e., heroin, barbiturates) cardiac care parallels current advanced cardiac life support guidelines,³⁶⁶ with a few exceptions.

Mechanisms: The ability of cocaine to increase myocardial oxygen demand secondary to induction of hypertension and tachycardia, while decreasing coronary blood flow through vasoconstriction, and induction of coronary thromboses (the latter due to enhancement of platelet aggregation) makes it an ideal precipitant of myocardial ischemia and infarction.^{367,368}

Benzodiazepines: In experiments in animals, benzodiazepines attenuate the cardiac and CNS toxicity of cocaine.^{123,124,369} Perhaps through their anxiolytic effects, benzodiazepines reduce blood pressure and heart rate, thereby decreasing myocardial oxygen demand.³⁶⁷ They are recommended as first-line agents for treatment of cocaine-intoxicated patients with myocardial ischemia who are anxious, have tachycardia, and/or are hypertensive.

Aspirin: Aspirin should be administered to help prevent the formation of thrombi in patients with suspected ischemia. This recommendation is based on theoretical considerations (e.g., decreasing platelet aggregation),^{370–372} the drug's good safety profile, and the extensive investigation of aspirin in patients with ischemic heart disease unrelated to cocaine. There are, however, no clinical data on the use of aspirin in patients with cocaine-associated myocardial ischemia.³⁶⁷

Nitroglycerin: Nitroglycerin is recommended as first-line therapy for cocaine-induced cardiac ischemia based on studies that show a reversal of cocaine-induced coronary artery vasoconstriction³⁵⁶ and reports of its ability to relieve cocaine-associated chest pain.³⁷³

Calcium-channel blockers: In studies of cocaine intoxication in animals, calcium-channel blockers prevent malignant arrhythmias,³⁷⁴ blunt negative inotropic effects,³⁷⁵ limit the increase in systemic vascular resistance,³⁷⁵ and protect against myocardial infarction.³³⁶ However, one study by Derlet et al.³⁷⁶ showed that calcium-channel blockers may increase CNS toxicity and mortality.³⁷⁶ This study, which was performed on rats, has been criticized on the basis that the cocaine was

administered intraperitoneally and that pretreatment with a calcium antagonist might have accelerated peritoneal absorption.³⁷⁷ Another study by Nahas et al.³⁷⁸ showed that nitrendipine (a calcium antagonist with good CNS penetration) protected rats against cocaine-induced seizures and lethality. Verapamil reverses cocaine-induced coronary artery vasoconstriction³⁷⁹ and may play a role in the treatment of refractory myocardial ischemia secondary to cocaine use.

Phentolamine: Phentolamine, an alpha-adrenergic antagonist, reverses cocaine-induced coronary artery vasoconstriction,³⁵¹ and electrocardiographic resolution of ischemia has been documented in some patients.³⁶⁷ The use of a low dose (1 mg) may avoid the hypotensive effects of the drug while maintaining the anti-ischemic effects.³⁸⁰

Beta-blockers: Because of their association with coronary vasoconstriction and conflicting animal studies (see previous section on hypertension), beta-adrenergic blockers are not routinely recommended for the treatment of cocaine-associated ischemic chest pain. However, esmolol is indicated for severe adrenergic crisis associated with tachycardia and hypertension. Esmolol or metoprolol may play a role in the treatment of cocaine-induced malignant ventricular ectopy if lidocaine and defibrillation fail³⁸⁰ (see section below on arrhythmias).

Thrombolytic therapy: Biogenic amines such as serotonin and epinephrine, which are released in large quantities by drugs such as cocaine, stimulate platelet aggregation. Stimulated platelets release thromboxane A₂, which exacerbates ischemia by increasing vasoconstriction. The activation of the coagulation cascade and the formation of thrombin clot may follow. Thus, thrombolytic therapy seems rational in the setting of cocaine-induced myocardial infarction. However, the safety of thrombolysis has been questioned by Bush³⁸¹ after one patient died of an intracerebral hemorrhage. A larger study by Hollander et al.³⁸² noted no such complications among 36 patients who received thrombolytic therapy. Although thrombolytic agents may be safe, several concerns persist among clinicians: First, the mortality from cocaine-associated myocardial infarction is extremely low in patients who reach the hospital alive (0/136 patients in one study).³⁸³ Second, the clinical benefit of thrombolytic therapy in cocaine-induced coronary thrombosis has not been demonstrated.³⁸² Finally, young patients with cocaine-associated chest pain have a high incidence of early repolarization (a variant of the normal ECG^{384,385}); as a result they may inadvertently receive thrombolysis when it is not necessary.^{381,384,385} Because of these concerns as well as the belief by some³⁸⁶ that the major mechanism of cocaine-mediated infarction is vasospasm, thrombolytic therapy is only recommended under the following circumstances: (1) when percutaneous coronary intervention and angioplasty is not available; (2) in acute myocardial infarction with an electrocardiogram with >2 mm ST-segment elevation in two or more contiguous *precordial leads*, or >1 mm ST-segment elevation in two or more contiguous *limb leads*; and (3) when no contraindications to thrombolytic therapy exist (Table 8.2.11). It is interesting to note that studies have shown significant coronary artery disease (i.e., stenosis > 50%) is present in up to 77% of patients with cocaine induced myocardial infarction.³⁸⁷

Lidocaine: Lidocaine, a sodium channel blocker, was initially thought to increase the risk of arrhythmias and seizures in patients with cocaine intoxication, based on studies in Sprague-Dawley rats.³⁸⁸ Recent evidence from dog³⁸⁹ and guinea pig hearts³⁹⁰ suggests that lidocaine competes with cocaine for binding sites at the sodium channels and is then rapidly released from the sodium channel without harmful effects. A retrospective review of 29 patients who received lidocaine in the context of cocaine-associated dysrhythmias showed no adverse outcomes.³⁹¹ Cautious use of lidocaine to treat ventricular arrhythmias occurring after cocaine use therefore seems reasonable. Ventricular arrhythmias that occur within a few hours after the use of cocaine may be the result of sodium channel blockade (e.g., quinidine-like effects) or from excessive levels of circulating catecholamines. For this reason cardioselective beta-blockers and/or sodium bicarbonate may be effective as well.³⁹²

Arrhythmias: Arrhythmias that occur after cocaine abuse may be associated with myocardial infarction, excessive catecholaminergic surge, and/or sodium channel blockade (e.g., “quinidine-like” effects).³⁹³

Table 8.2.11 Contraindications to Thrombolytic Therapy

Absolute Contraindications
Active internal bleeding
Altered consciousness
Cerebrovascular accident (CVA) in the past 6 months or <i>any</i> history of hemorrhagic CVA
Intracranial or intraspinal surgery within the previous 2 months
Intracranial or intraspinal neoplasm, aneurysm, or arteriovenous malformation
Known bleeding disorder
Persistent, severe hypertension (systolic BP > 200 mm Hg and/or diastolic BP > 120 mm Hg)
Pregnancy
Previous allergy to a streptokinase product (this does not contraindicate tPA administration)
Recent (within 1 month) head trauma
Suspected aortic dissection
Suspected pericarditis
Trauma or surgery within 2 weeks that could result in bleeding into a closed space
Relative Contraindications
Active peptic ulcer disease
Cardiopulmonary resuscitation for > 10 min
Current use of oral anticoagulants
Hemorrhagic ophthalmic conditions
History of chronic, uncontrolled hypertension (diastolic BP > 100 mm Hg), treated or untreated
History of ischemic or embolic CVA > 6 months ago
Significant trauma or major surgery > 2 weeks ago but < 2 months ago
Subclavian or internal jugular venous cannulation

Source: Adapted from National Heart Attack Alert Program Coordinating Committee 60 Minutes to Treatment Working Group, NIH Publication No. 93-3278. September 1993, p. 19.

Supraventricular arrhythmias: Supraventricular arrhythmias due to cocaine include paroxysmal supraventricular tachycardia, rapid atrial fibrillation, and atrial flutter.³⁹⁴ These arrhythmias are usually short-lived and if the patient is hemodynamically stable do not require immediate therapy.^{395–397} Benzodiazepines modulate the stimulatory effects of cocaine on the CNS^{154,170,398} and may blunt the hypersympathetic state driving the arrhythmia. Patients with persistent supraventricular arrhythmias should be treated initially with a benzodiazepine (i.e., lorazepam or diazepam), and then if necessary with a cardioselective beta-blocker such as esmolol (see discussion under stepwise approach to management). Unstable supraventricular rhythms should be managed in accordance with the American Heart Association's American Cardiac Life Support (ACLS) protocols.

Ventricular arrhythmias (stable): As with supraventricular arrhythmias from cocaine, ventricular ectopy and short runs of ventricular tachycardia (VT) are usually transient, and most often resolve with careful observation supplemented by titrated doses of a benzodiazepine.³⁶⁶ In cases with persistent ventricular ectopy, cardioselective beta-blockers (i.e., metoprolol or esmolol) may reverse excessive catecholaminergic stimulation and suppress the ectopy. Lidocaine may also be of benefit.^{123,399,400}

Ventricular arrhythmias (unstable): Ventricular fibrillation (VF) and malignant VT (VT) with hypotension, or evidence of congestive heart failure, or ischemia, should initially be treated as recommended by the ACLS algorithm. Lidocaine (1.0 to 1.5 mg/kg) may be given with caution as previously discussed. Defibrillation should proceed as usual.³⁶⁶

Epinephrine: Concerns about epinephrine have been raised since it has similar cardiovascular effects as cocaine and may even mediate many of its effects. There is, however, no good evidence to suggest eliminating the initial epinephrine dose in treating cocaine-induced VF. Clinicians should, however, increase the interval between subsequent doses of epinephrine to every 5 to 10 min and avoid high-dose epinephrine (greater than 1 mg per dose) in refractory patients.³⁶⁶

Propranolol or other beta-blocker: Propranolol continues to be recommended by the Committee on Emergency Cardiac Care for the treatment of malignant cocaine-induced VF and VT. This recommendation is based on animal data and empiric reports but is not supported by any

human studies.^{154,369,401,402} The risk of beta-blockade in cocaine toxicity is that of unopposed alpha-stimulation resulting in severe hypertension, as well as coronary vasoconstriction.³⁴¹ This is of less concern with the use of a cardioselective beta-blocker such as esmolol or metoprolol.

8.2.7.2 Stepwise Approach to Management

Immediate Interventions

1. Airway, Breathing, Circulation: Maintain the airway and assist ventilation if necessary. Administer supplemental oxygen. Treat hypotension, and resuscitate as per previous reviews.^{3,366}

2. Antidotes: Administer appropriate antidotes, including 25 g dextrose IV if the patient is hypoglycemic, as per the Section 8.2.1 on coma.

3. IV, Monitor, O₂: Administer oxygen by nasal cannula at 4 L/min, monitor cardiac status (obtain ECG) and start a peripheral intravenous line. Hang normal saline to keep vein open.

4. Benzodiazepines: Administer a benzodiazepine (i.e., 0.25 to 0.5 mg, or 2 to 4 mg IVP lorazepam) if the patient is anxious, hypertensive, or is experiencing cardiac chest pain or transient arrhythmias.

5. Sublingual and transdermal nitroglycerin/aspirin: If hemodynamically stable but chest pain persists, administer nitroglycerin sublingually (up to three tablets or three sprays of 0.4 mg each). Apply a nitroglycerin paste, 1 in., to the chest. Give one aspirin (325 mg) by mouth.

6. IV nitroglycerin: If chest pain is present and the patient is hemodynamically stable, begin a nitroglycerin drip starting at 8 to 10 µg/min. Titrate upward to control of pain if blood pressure remains stable.

7. Calcium-channel blocker: Consider the use of calcium-channel blocker such as verapamil (5.0 mg IV over 2 min, with a repeat 5 mg dose IV if symptoms persist) or diltiazem (0.25 mg/kg IV over 2 min, with repeat dose of 0.35 mg/kg IV over 2 min if symptoms persist) for resistant myocardial ischemia. Consider administration of **morphine sulfate** for chest pain if hemodynamically stable (2.0 mg IVP with additional doses titrated to control pain and anxiety).

8. Phentolamine: Use phentolamine, 1.0 to 5.0 mg IVP for resistant chest pain.

9. Thrombolytics: If ECG shows new ST segment elevation (greater than 2 mm in two consecutive leads) that persist despite nitrates or calcium-channel blockers, no contraindications exist (Table 8.2.11), and percutaneous coronary intervention is not readily available, administer a thrombolytic agent (Table 8.2.12, dosing). See previous reviews for comprehensive guide to thrombolytics.^{403–406}

Comment: Establish two peripheral IVs, and perform a 12-lead ECG q 30 min until infusion completed. Avoid all unnecessary venous and arterial sticks and beware that automated blood pressure cuffs, nasogastric tubes, Foley catheters, and central lines are associated with increased bleeding.⁴⁰⁷

10. Arrhythmias:

Supraventricular arrhythmias: See discussion above. Generally, treatment parallels ACLS guidelines with the use of benzodiazepines and beta-blockers in the doses recommended below.

Ventricular arrhythmias: If stable ventricular tachycardia does not respond to benzodiazepines (i.e., lorazepam 0.25 to 0.50 mg/kg or 2 to 4 mg IVP) it should be treated with lidocaine (1.5 mg/kg IVP) and/or beta-blockers (metoprolol 5.0 mg IV every 5 min, to a total of 15 mg; or esmolol, load with 500 µg/kg/min over 1 min and run a maintenance infusion at 50 to 200 µg/kg/min; or propranolol, 1.0 mg IV every 5 min to a total of 3 mg). Esmolol has the advantage of being a beta-1, cardioselective agent with a short half life ($t_{1/2}$ = 9 min) allowing it to be rapidly discontinued in the event of an adverse reaction. Unstable ventricular tachycardia should be treated with immediate cardioversion or defibrillation (see ACLS recommendations on VT, VF) along with the administration of lidocaine, beta-blockers, and benzodiazepines. Patients should be reshocked after each administration of lidocaine or beta-blocker.³⁶⁶ The quinidine-like effects of cocaine are man-

Table 8.2.12 Current Thrombolytic Agents and Their Dosing in the Acute MI Patient

Drug	Dose	Comments
Streptokinase (SK) (Cost \$300) ^a	1.5 million units IV over 60 min	SK is antigenic; allergic reaction and rarely anaphylaxis (<1% incidence) may occur. Administration may cause hypotension, necessitating a slower infusion rate than that recommended. SK may not be effective if administered 5 days to 6 months after prior SK therapy or 12 months after APSAC therapy or a streptococcal infection.
APSAC (Anistreplase) (Cost \$1675) ^a	30 units IV over 2–5 min	APSAC is also antigenic and its administration may be complicated by hypotension (see above). APSAC may not be effective if administered 5 days to 12 months after prior SK or APSAC therapy or a streptococcal infection.
Reteplase (Retavase) (Cost \$3200) ^a	10 units IV over 2 min, followed by a second dose of 10 units IV over 2 min, 30 min after the first dose	Fast, convenient double-bolus dosing. Unlike SK and APSAC, reteplase is not antigenic. Hypotension complicating infusion is less likely than with either SK or APSAC. A slightly higher incidence of cerebral hemorrhage has been noted compared with SK.
tPA (Alteplase) (Cost \$3200) ^a	“Front-loaded” dosing: 15 mg IV over 2 min, followed by 0.75 mg/kg (50 mg maximum) IV over 30 min, followed by 0.5 mg/kg (35 mg maximum) IV over 60 min	Do not exceed the maximum dose of 100 mg. Unlike SK and APSAC, tPA is not antigenic. Hypotension complicating infusion is less likely than with either SK or APSAC. A slightly higher incidence of cerebral hemorrhage has been noted compared with SK.
Tenecteplase (TNKase) (Cost \$2850)	A single bolus dose should be administered over 5 s based on patient weight (30–50 mg)	Ease of administration, but may not stop infusion once given. Similar efficacy and complication rate as tPA.

^a Average wholesale price to the pharmacy.

ifested by a wide complex sinus rhythm and frequently respond to boluses of sodium bicarbonate (50 mEq IV, repeat every 5 min to a total of 150 mEq). A bicarbonate drip (made by adding two to three ampoules of sodium bicarbonate in one liter of D5W) may be run simultaneously at 200 cc/h.

Comment: Caution should be taken to avoid hypernatremia or hypervolemia and resulting pulmonary edema from overzealous sodium bicarbonate administration. Also, class IA and IC antiarrhythmic agents (i.e., procainamide, dysopyramide, quinidine, propafenone) are contraindicated in the setting of drug-induced conduction blockade as is occasionally seen with cocaine.^{390,392,408}

Secondary Interventions

- 1. Repeat ECG:** Repeat ECG if chest pain worsens or recurs.
- 2. Chest radiograph:** To further assess for congestive heart failure or evidence of cardiomyopathy; also to assess for pneumothorax, or pneumomediastinum.
- 3. Monitoring:** A minimum of 12 h of cardiac monitoring is recommended for patients with chest pain associated with cocaine use (see section on disposition).
- 4. Coronary Stress Testing:** Because patients with cocaine-associated chest pain have a 1-year survival of 98% and an incidence of late myocardial infarction of only 1%, urgent cardiac evaluation is probably not necessary for patients in whom acute myocardial infarction has been ruled out.³⁶⁷ However, keep in mind that patients who rule in for cocaine-induced myocardial infarction, despite an average age of 32 to 38 years, have a 31 to 67% incidence of significant underlying coronary artery disease.
- 5. Laboratory Data:** Baseline laboratory data should include a CBC, PT/PTT, cardiac isoenzymes including creatine kinase MB, troponin T, as well as electrolytes. Repeat isoenzymes every 8 to 12 h.

Comment: Rhabdomyolysis may complicate cocaine intoxication and as a result increased concentrations of myoglobin, creatine kinase, and creatine kinase MB may occur even in the absence of myocardial infarction.⁴⁰⁹ After using cocaine, approximately 50% of patients have elevations in the serum creatine kinase concentration whether or not they are experiencing a myocardial infarction.⁴¹⁰ If the patient has a continuously rising enzyme concentration this is much more likely to represent a true myocardial infarction.^{383,410} The immunoassay for cardiac troponin I has no detectable cross-reactivity with human skeletal muscle troponin I, making it a more specific test than that for creatine kinase MB in assessing myocardial injury when skeletal-muscle injury also exists.^{411,412} However, troponin I is a late marker for myocardial infarction with improved sensitivity after 12 h (95 to 100%) vs. CK-MB, which is usually elevated within 6 to 8 h.⁴¹³

6. Disposition

- a. **Intensive care unit:** All patients with evidence of acute myocardial infarction, or any unstable patient.
- b. **Telemetry:** Hemodynamically stable patients without ongoing chest pain, ECG changes, or elevated cardiac isoenzymes to a monitored observation unit for a minimum of 12 h of monitoring and serial creatine-kinase MB measurements and repeat ECGs. Patients who have no evidence of ongoing chest pain with normal ECG and cardiac isoenzymes after 12 h may be discharged.
- c. **Home:** Selected patients who have normal ECG, cardiac enzymes, and no evidence of ongoing ischemia may be discharged after a period of 9 to 12 h.

Comment: Observation periods to 9 to 12 h to rule out myocardial infarction in low-risk patients with chest pain unrelated to cocaine use have become more common.^{414–416} Similar observation periods may be appropriate for many patients with cocaine-associated chest discomfort since these patients appear to have a low incidence of cardiovascular complications, whether or not they have myocardial infarction.⁴¹⁷ Of patients with cocaine-associated chest pain, approximately 6% will have a myocardial infarction.^{384,410,418} Of those patients with cocaine-associated myocardial infarction, 36% will go on to develop cardiovascular complications.³⁸³ Of those who develop cardiovascular complications 94–100% can be detected by the use of ECG, serial creatine kinase MB measurements, and observation for 12 h.³⁸³

8.2.8 Stroke

8.2.8.1 General Comments

Any physician treating a patient who has suffered a stroke must consider drug abuse in the differential diagnosis, especially if the patient is young.^{419–424} In a study done at San Francisco General Hospital, drug abuse was identified as the most common predisposing condition among patients under 35 years of age presenting with stroke.⁴²⁵ Most patients had either infective endocarditis (13/73) or stroke occurring soon after the use of a stimulant (34/73). Kaku and Lowenstein⁴²⁵ estimated that the relative risk for stroke among drug abusers after controlling for other stroke risk factors was 6.5.

Mechanism: Acute stroke associated with drugs of abuse may result from hemorrhage, vasoconstriction, severe hypertension, hypotension, embolism of foreign materials (i.e., talc, ground up tablets, etc.; see Table 8.2.5 through Table 8.2.7) via a patent foramen ovale, vasculitis, cardiac thrombi, endocarditis, and opportunistic infection.⁴²⁶ Among patients with stroke from cocaine abuse about 50% have cerebral hemorrhage, 30% subarachnoid hemorrhage, and 20% have ischemic stroke.^{427,428} The pathophysiologic mechanisms involved are thus much different than for the general population, where the overwhelming majority of strokes are ischemic (80%) in origin and only 10% result from hemorrhage.⁴²⁹ This difference makes the treatment of drug-induced stroke significantly different. Instead of anticoagulation or internal carotid artery surgery, the drug-abusing

patient may be more appropriately treated with steroids for vasculitis, antibiotics for endocarditis, or calcium-channel blockers for vasospasm.

Thrombolytics: There is substantial disagreement in the literature regarding the safety and efficacy of thrombolytic therapy for ischemic strokes. Data from the five completed randomized trials evaluating the use of intravenous thrombolytics in the treatment of ischemic strokes (ECASS,⁴³⁰ MAST-I,⁴³¹ NINDS,⁴³² MAST-E,⁴³³ and ASK⁴³⁴) involve a total of more than 2500 patients, but these studies used two different thrombolytic agents — tissue plasminogen activator (tPA) and streptokinase (SK) — that were given at different doses, with different adjunctive treatments, and with very different inclusion criteria. Thus it is impossible to pool the data for meta-analysis. Analyzing the studies individually, however, reveals that all three of the SK trials found excess mortality in the SK group that was both statistically and clinically significant, as did one of the two studies that used tPA. The fifth study, the NINDS trial, is the only one of the five to find outcome benefit in treated patients. The patients in the NINDS study all received thrombolytics within a 3-h time interval, which required rapid CT and radiologist review of the results before treatment could begin. These strict exclusion criteria would result in the treatment of only a very small percentage of stroke victims^{434a} (less than 5%). Furthermore, the increased risk of bleeding associated with thrombolytics would be imposed upon a number of patients who did not require treatment. Libman and colleagues⁴³⁵ reported that about 20% of the time when members of the trained acute stroke intervention team at their institution diagnosed stroke on clinical grounds prior to CT scan, the ultimate diagnosis proved to be different. Although treatment depended on CT results, in over half of the patients misdiagnosed clinically the CT scan also returned a result entirely compatible with stroke. Of these, 13 patients were postictal, 13 had systemic infections as the cause of their “stroke mimic,” and 10 had an ultimate diagnosis of toxic-metabolic cause. Because of the controversy surrounding ischemic strokes, and because of the increased risk of intracerebral hemorrhage (from uncontrolled hypertension; seizures; cerebral aneurysms, and vasculitis), thrombolytics are not recommended at this time for the treatment of drug-induced stroke.

Heparin: Although heparin has been recommended for the treatment of crescendo transient ischemic attacks (TIAs), strokes with a cardioembolic source, and posterior circulation strokes,^{436–438} it should be used with extreme caution in patients with drug-induced strokes because of the higher potential for hemorrhage (i.e., ~50%).

Antibiotics: Stroke complicates approximately 20% of all cases of endocarditis, with an overall mortality rate for endocarditis-associated strokes of 20%.^{439,440} Fortunately, the risk of recurrent embolism is low when infection is controlled (0.3%/day),⁴⁴⁰ obviating the need for anticoagulation despite that most endocarditis-related strokes are due to embolism from cardiac vegetations.^{439,440} Present recommendations for empiric antibiotic treatment are nafcillin 2.0 g q 4 h IV + gentamicin 1.0 mg/kg q 8 h IM or IV. If the patient is penicillin allergic give vancomycin 1.0 g q 12 h IV + gentamicin 1.0 mg/kg q 8 h IM or IV.

Surgery: Foreign body emboli most often have followed injection of crushed tablet preparations meant for oral use, especially methylphenidate (Ritalin) and pentazocine plus tripeleennamine (“T’s and Blues”).^{441,442} Patients dissolve tablets or capsules in water and filter them to varying extents, and then inject them. Showers of insoluble fillers (principally talc) enter the circulation⁴¹⁹ and lodge in the lung, forming granulomas. Granulomas may also form in the lung and brain (possibly due to the passage of foreign materials through a patent foramen ovale), and may require surgical intervention. Surgery may also be required for decompression of cerebral hematomas, repair of ruptured aneurysms, and the removal of abscesses.

Nimodipine: Cocaine is known to decrease reuptake of serotonin, which is believed to play a role in cocaine-induced headaches and may be associated with cocaine-induced vasoconstriction.^{443–445} Rothrock et al.⁴⁴⁶ reported on three cases of amphetamine-related stroke: in one case a 35-year-old abuser had 20 episodes of transient right hemiparesis occurring within minutes of inhaling methamphetamine; later he developed permanent right hemiparesis. In animal studies, intravenous methamphetamine administration has resulted in narrowing of the middle cerebral

artery branches within 19 min.⁴⁴⁷ While the pharmacologic approaches to cerebral vasospasm are varied, the calcium-channel blocker nimodipine has been used widely with proven efficacy in preventing vasospasm associated with hemorrhagic stroke.^{448,449} No studies looking at this issue in the setting of drug-induced hemorrhagic stroke exists. Although two animal studies^{450,451} found that nimodipine potentiated the toxicity of cocaine and amphetamines in rats, it is felt that in selected patients the risk–benefit ratio may favor nimodipine administration. Such populations may include the drug-abusing patient who is experiencing transient ischemic attacks closely temporally related to substance abuse or who has had a documented subarachnoid hemorrhage associated with cerebral vasospasm. Recent reports suggest no benefit of nifedipine in ischemic strokes of any type.⁴⁵²

Glucocorticoids/cyclophosphamide (vasculitis): Vasculitis has been associated with nearly every drug of abuse (ephedrine,⁴⁵³ pentazocine and tripeleminamine,⁴⁴² amphetamines,^{447,454,455} phenylpropanolamine,⁴⁵⁶ heroin,^{457,458} methylphenidate,⁴⁵⁹ pseudoephedrine,³²³ and cocaine^{460–463}). In the case of drug-induced vasculitis, removal and discontinuance of the offending agent is essential. While not considered emergency therapy, the combination of cyclophosphamide and prednisone may be of benefit in the treatment of drug-induced vasculitis and resulting stroke. Salanova⁴⁶⁴ and Glick³²³ reported on two cases of amphetamine- and phenylpropanolamine-induced vasculitis that had improvement documented angiographically with combination cyclophosphamide and prednisone. This combination therapy is also recommended for the treatment of other life-threatening vasculitides including polyarteritis nodosa (PAN) and Wegener’s granulomatosis.⁴⁶⁴

Comment: Many reports of drug-induced vasculitis are based on angiographic findings of segmental narrowing and dilations of distal intracerebral arteries. Although such signs are characteristic of cerebral vasculitis, they are nonspecific features of vascular injury, and can also be caused by vasospasm (secondary to a drug’s action or to subarachnoid hemorrhage), fibromuscular dysplasia, atherosclerosis, and cerebral emboli.⁴⁶⁵ Biopsy is recommended to determine which patients should receive appropriate therapy.

Acute hypertension: Acute, severe hypertension from stimulants such as cocaine and amphetamines can increase vascular intraluminal pressures, cause turbulent blood flow, and weaken the endothelium, leading to hemorrhage and thrombosis. Severe hypertension should therefore be controlled (see Section 8.2.6 on hypertension). Moderate hypertension, however, may be a homeostatic response designed to maintain intracerebral blood flow in the presence of intracranial hypertension. In this case, blood pressure should not be lowered, or, if there is ongoing evidence of sympathomimetic drug intoxication, it should be lowered gradually to a diastolic blood pressure in the 100 to 110 mm Hg range. Clinical judgment should be used in this setting since decreasing blood flow to “watershed” areas or borderline ischemic zones with poor collateral circulation may lead to larger neurological deficits.^{466–468}

8.2.8.2 Stepwise Approach to Management

Immediate Interventions

1. Airway, Breathing, Circulation: Maintain the airway and assist ventilation if necessary. Administer supplemental oxygen. Treat hypotension, and resuscitate as per previous reviews.^{3,366} If the patient requires rapid sequence intubation consider using an agent such as pentobarbital, 5 mg/kg, or thiopental, 3 to 5 mg/kg, that will both lower intracranial pressure and decrease risk of seizures. Do not give barbiturates to a hypotensive patient. Lidocaine, 100 mg, prior to intubation is helpful in attenuating the rise in intracranial pressure seen with laryngoscopy.^{469,470}

2. Antidotes: Administer appropriate antidotes, including 25 g dextrose IV if the patient is hypoglycemic, as per Section 8.2.1 on coma. Even focal findings may be caused by hypoglycemia; a focal neurologic finding occurs in about 2.5% of hypoglycemic patients.⁴⁷¹

3. IV, Monitor, O₂: Administer oxygen by nasal cannula at 4 L/min. Monitor cardiac status (obtain ECG) and start a peripheral intravenous line. Hang normal saline to keep vein open.

4. Herniation and increased intracranial pressure: Hyperventilation (to a $p\text{CO}_2$ of 30 to 35 mm Hg), mannitol (0.5 g/kg over 20 min IV), and possibly furosemide (10 mg IV) are indicated for evidence of *progressive* mass effect, shift, or herniation. Limit IV fluids to avoid cerebral edema.

5. Control agitation: An agitated patient with ongoing sympathomimetic effects of stimulants (delirium, psychosis, and agitation) should be sedated with benzodiazepines as discussed in Section 8.2.2. Straining, struggling, or arguing could elevate intracranial pressure and increase the risk of exacerbating a hemorrhagic stroke. Neuromuscular paralysis with endotracheal intubation and mechanical ventilation may be necessary.

6. Control seizure activity: Due to their ability to lower intracranial pressure barbiturates may be preferred for seizure control if the patient has evidence of increased intracranial pressure. Benzodiazepines are still recommended for the rapid initial management (Section 8.2.3, seizures).

7. Control nausea and vomiting: For the same reasons discussed above. Use something that will not lower the seizure threshold such as prochlorperazine. Instead, try metoclopramide 10 to 50 mg IVP.

8. Hypertension: Antihypertensive therapy is not usually necessary in the emergency department. Exceptions may be patients in whom acute ongoing drug intoxication is apparent. It should be kept in mind that the more severe the stroke, the greater the homeostatic, hypertensive response.

9. CT of the brain: Perform a CT of the brain without contrast on all the following patients:

- a. Patients with focal neurological deficits
- b. Patients with altered mental status that does not rapidly return to normal after a brief period of observation
- c. Patients who complain of severe rapid onset of headache that persists after sedation, and minor pain medications

10. Laboratory Data: Baseline laboratory data should include CBC, platelets, PT/PTT, electrolytes, and sedimentation rate. Perform CPK isoenzymes if the patient has chest pain, or is obtunded to rule out myocardial infarction. Draw blood cultures if endocarditis is suspected. While the use of toxicology screens of blood and urine are generally overutilized,⁵ they are recommended if diagnosis remains questionable.

Secondary Interventions

1. Monitor and reassess: Closely monitor neurological status for signs of deterioration.

2. ECG: Perform ECG to determine underlying cardiac rhythm.

3. Seizure prophylaxis: Phenobarbital 15 mg/kg IV over 20 min, as prophylaxis in hemorrhagic strokes. Fosphenytoin may be considered as an alternative although is considered less effective for drug related seizures.

4. Autonomic instability: Extreme fluctuations in blood pressure and heart rate are often the result of excessive autonomic discharge associated with hemorrhagic stroke and may, in severe cases, be treated with esmolol or labetalol (see hypertension).

5. Echocardiogram, blood cultures: Transthoracic echocardiography is a useful noninvasive diagnostic test for endocarditis, which is approximately 80% sensitive in finding vegetations on native and bioprosthetic valves.⁴⁷² Transesophageal echocardiography (not usually available in the emergency department) is preferred for the detection of valvular vegetations due to increased sensitivity, especially if the patient has mechanical prosthetic valves that may produce artifact from the metallic components.⁴⁷³ Obtain three blood cultures to increase sensitivity to greater than 95% in the febrile patient.⁴⁷⁴

6. Thrombolytics/heparin: Avoid thrombolytics and use heparin sparingly (e.g., only in those patients with evidence of crescendo transient ischemia in consultation with a neurologist, in patients who have had hemorrhagic stroke ruled out).

7. Angiogram: If the stroke is hemorrhagic or if the patient has evidence of endocarditis, consider performing a cerebral angiogram to rule out vasculitis/aneurysm.

8. Nimodipine: Nimodipine, 60 mg PO q 6 h should be considered in all patients with subarachnoid hemorrhage and others with evidence of recent drug abuse and stuttering onset or progression of symptoms suggestive of acute vasospasm.

9. Biopsy: Surgical biopsy should be performed when the diagnosis of *vasculitis* is suggested by angiogram and yet still remains in question. Alternatively, if the patient requires surgery for any other reason (i.e., intracerebral hematoma) a biopsy can be done at that time. Because there seems to be discernible histological differences between drug-induced and primary CNS vasculitis, leptomeningeal biopsy may be the definitive means of differentiating these two entities.³²³

10. Disposition: All patients with drug-induced stroke should be admitted to the hospital for thorough evaluation. Likewise all patients with drug-induced TIAs should be admitted to the hospital.

8.2.9 Ingestions and Decontamination

8.2.9.1 General Comments

Ingestion vs. “packing” or “stuffing”: Definitions of the terms ingestion, packing, and stuffing are required to understand the different approaches to decontamination that are recommended here. *Ingestions* occur when drugs of abuse are taken orally as a method of inducing a “high” or as a suicidal attempt. *Body packing* refers to the use of the human gastrointestinal (GI) tract for purposes of drug smuggling.^{475–477} Smugglers or “mules” ingest a drug, usually cocaine or heroin, in carefully wrapped high-grade latex, aluminum foil, or condoms designed to prevent leakage. Case reports even describe the use of children who are forced to consume large numbers of drug-containing packets.⁴⁷⁸ Each packet typically contains potentially lethal amounts of drug (a typical packet of cocaine contains 5 to 7 g; lethal dose = 1.0 to 1.2 g in a human). *Body stuffing* refers to the act of swallowing poorly wrapped “baggies,” vials, or other packages filled with illegal drugs in an attempt to conceal them from the police. Baggies or vials may or may not contain lethal amounts of drug. A variant of body stuffing is the ingestion of drugs to produce an acute medical condition that could necessitate medical intervention, thereby deferring incarceration⁴⁷⁹ (see Table 8.2.13).

Methods of decontamination:

Gastric lavage: Gastric lavage has been a widely accepted medical treatment for ingested poisons.⁴⁸⁰

Opposed to this practice are four large prospective, randomized, controlled studies in humans involving a total of 2476 patients, which have consistently failed to support the routine use of gut emptying. Kulig et al.⁴⁸¹ demonstrated that poisoned patients receiving charcoal alone without prior gut emptying had no significant difference in clinical outcome compared to patients who were treated with both gastric lavage and activated charcoal. The exception was a small subset ($n = 16$) of patients who were obtunded on presentation and were lavaged within 1 h of ingestion. Albertson et al.⁴⁸² compared the clinical effectiveness of syrup of ipecac and activated charcoal to that of activated charcoal alone in the treatment of 200 patients with mild to moderate toxic ingestions. Patients receiving only activated charcoal were discharged from the emergency department in significantly less time than those receiving both syrup of ipecac plus activated charcoal. Merigian et al.⁴⁸³ evaluated 808 patients with ingestions and found no benefit from gastric emptying with administration of activated charcoal compared to activated charcoal alone. Moreover, gastric lavage was associated with a higher incidence of medical intensive care unit admissions and aspiration pneumonia in this study. Most recently, Pond et al.⁴⁸⁴ performed a prospective, controlled study of 876 patients and concluded that gastric emptying is unnecessary in the treatment of acute overdose regardless of severity of intoxication and promptness of presentation.

Recommendation: Based on these studies, there is little support for routine use of gastric lavage in the drug abusing patient who presents to the emergency department after an ingestion. An exception

Table 8.2.13 Comparison of Body Packers and Body Stuffers

	Body Packer	Body Stuffer
Profile	Returning from trip abroad; found in airports or at border crossings	Encountered on street or in drug raid, often arrested for dealing or other charge; may be chronic drug abuser or known drug dealer
How brought to attention	Deny drug ingestion; serious symptoms (seizure, respiratory arrest) or asymptomatic; diagnosis by radiograph or physical examination; likely to have a diagnostic radiograph or rectal examination	Seen taking drugs, or found symptomatic in jail; radiograph tends to be of little diagnostic help
Drugs involved	High-profit drug (e.g., cocaine or heroin)	Any drug sold on street, including hallucinogens or sedatives; often involves more than one drug
Packaging material	High-grade latex, aluminum foil, or condoms designed to prevent leakage Large amount of drugs per package.	Loosely wrapped in paper or foil; single doses or free drug
Treatment	Usually observation; surgery for intestinal obstruction; value of charcoal or cathartic unknown; treat if symptoms develop	Gastric emptying and activated charcoal and cathartic; observe and treat symptomatically
Clinical course	Rupture of single package may be fatal because of the large amount of drug per package; specific toxic syndromes may be present, e.g., narcotic or cocaine toxicity	Variable symptoms, often from a mixed drug overdose; may have acute laryngeal obstruction

may be the patient who has swallowed an extremely large quantity of drug and presents within 30 to 60 min.

Activated charcoal: Activated charcoal given orally has been proved to be as effective as gastric emptying followed by activated charcoal in the studies described above. In other studies involving volunteers, activated charcoal was shown to be superior to ipecac-induced emesis, or gastric lavage.^{485,486} A dose of 50 to 100 g of activated charcoal is generally sufficient to bind the drug and prevent absorption, although this may vary depending on the drug and the amount that was taken. This 50 to 100 g dose was based on a study in which healthy volunteers were given up to 5 g of para-aminosalicylate (PAS).⁴⁸⁷ The fraction of unadsorbed PAS decreased from 55 to 3% as the charcoal-to-PAS ratio increased from 1:1 to 10:1. Activated charcoal is relatively safe, although vomiting and diarrhea are seen commonly when cathartics such as sorbitol are added, and constipation can result if cathartics are withheld. Serious adverse effects include pulmonary aspiration of activated charcoal along with gastric contents;^{488–490} significant morbidity from spillage of activated charcoal in the peritoneum after perforation from gastric lavage;⁴⁹¹ and intestinal obstruction and pseudo-obstruction,^{492–494} especially following repeated doses of activated charcoal in the presence of dehydration.

Recommendation: Activated charcoal is recommended in all cases of orally administered drug intoxication except if the drug is not bound by charcoal (e.g., lithium, iron, alcohols).

Multiple-dose activated charcoal: Multiple-dose activated charcoal (MDAC), sometimes referred to as “gastrointestinal dialysis,” is thought to produce its beneficial effect by interrupting the enteroenteric and in some cases, the enterohepatic re-circulation of drugs.⁴⁹⁵ In addition, any remaining unabsorbed drug may be adsorbed to the repeated doses of activated charcoal. Phenobarbital is the only drug of abuse for which there is evidence from both clinical and experimental studies in animals and volunteers that drug elimination is increased by the use of MDAC.⁴⁹⁵ Pharmacokinetic data would also support the use of MDAC for carbamazepine, theophylline, aspirin, dapsone, and quinine ingestions.⁴⁹⁵ Pond et al.⁴⁹⁶ performed a controlled trial of ten comatose patients who overdosed on phenobarbital. In this study, the control and treatment groups both received 50 g activated charcoal on presentation and, in addition, patients in the treatment group were given 17 g activated charcoal together with sorbitol every 4 h until they could be extubated. Although the mean elimination half-life of phenobarbital was shortened (36 ± 13 h vs. 93 ± 52 h), the length of time the patients in each group required mechanical ventilation or stayed in the hospital did not differ significantly. This study suggested that acute tolerance to the effects of the drug obviated the

benefit of faster drug elimination. Another study looking at a series of six patients given charcoal in larger doses and without cathartic showed enhanced elimination of phenobarbital, and also decreased time to recovery.⁴⁹⁷ Beware of inducing aspiration with MDAC. Other adverse effects including obstipation and appendicitis have been described with MDAC.⁴⁹⁸

Recommendation: MDAC is recommended in cases in which there may be large quantities of drug in the intestinal tract (i.e., body packers or body stuffers) and in selected cases of phenobarbital overdose (i.e., comatose patients who have not received hemoperfusion).

Whole bowel irrigation: Whole bowel irrigation (WBI) involves the administration of large volumes (2 L/h in an adult, 0.5 L/h in a child) of polyethylene glycol electrolyte lavage solution (PEG-ELS) per nasogastric tube to flush out the gastrointestinal tract and decrease the time available for drug to be absorbed. It has been used effectively in the management of iron,^{499–501} sustained-release theophylline,⁵⁰² sustained-release verapamil,^{503,504} sustained release fenfluramine,⁵⁰⁵ zinc sulfate,⁵⁰⁴ and lead,⁵⁰⁶ and for body packers.^{475,507} Because of its balanced electrolyte content and iso-osmolar nature, PEG-ELS use results in minimal net water and electrolyte shifts, and is safe and effective under the right circumstances. In the case of body packers, the excellent bowel cleansing from WBI may reduce morbidity should bowel perforation occur or surgery be required.⁴⁷⁵ In a case described by Utecht et al.⁵⁰⁷ 10-g packets of heroin wrapped in electrician's tape appeared to be dissolved by 8 L of PEG-ELS solution. Endoscopy showed this patient to have only electrician's tape left in his stomach after WBI, suggesting the heroin initially present had been dissolved by the WBI solution. Polyethylene glycols are used extensively in pharmaceutical manufacturing as solubilizing agents and it has been shown that PEG 4000, a water-soluble polymer comparable to the polymer used in PEG-ELS, can increase the dissolution rates of poorly water-soluble drugs.⁵⁰⁸ Alkaloidal heroin is poorly water soluble; 1 g dissolves in 1700 ml of water.⁵⁰⁹ Therefore, the large amount of heroin, 10 g in each package, would not have been solubilized in the stomach by water alone. The patient had continuing absorption of heroin despite the administration of multiple doses of activated charcoal. Rosenberg⁵¹⁰ has shown that the antidotal efficacy of oral activated charcoal was markedly diminished by PEG-ELS in volunteers treated with aspirin. Tenenbein⁵¹¹ likewise reported that PEG-ELS binds to charcoal and that this interferes with aspirin adsorption by activated charcoal.

Recommendation: WBI is recommended in cases involving body packers. WBI is also recommended in situations in which large amounts of drug may still be present in the gastrointestinal tract due to concretions (common with glutethimide, and meprobamate) or when a sustained release preparation (i.e., sustained release morphine) has been ingested. Because WBI may solubilize heroin and may diminish the efficacy of activated charcoal the use of activated charcoal and cathartics is preferred over WBI for treatment of heroin body packers.

8.2.9.2 Stepwise Approach to Management

Immediate Interventions

1. Airway, Breathing, Circulation: Maintain the airway and assist ventilation if necessary. Administer supplemental oxygen. Treat hypotension, and resuscitate as per previous reviews.^{3, 90}

2. IV, Monitor, O₂: Administer oxygen by nasal cannula at 4 L/min, monitor cardiac status (obtain ECG), and start a peripheral intravenous line. Hang normal saline to keep vein open.

3. Gastric lavage: Not recommended unless patient has ingested massive quantities and arrives within 30 min to 1 h of ingestion.

4. Activated charcoal: Administer activated charcoal 50 to 100 g PO. Try to obtain a 10:1 ratio of activated charcoal to drug by weight if possible. If unable to administer enough activated charcoal on the first dose repeat the dose in 4 h. Multiple-dose activated charcoal: give 12.5 g/h or 25 g every 3 to 4 h. Studies have shown that the administration of hourly activated charcoal produces a shorter half-life than less frequent dosing, even though the same dose was administered over the same treatment period.^{512,513}

Comment: Administer MDAC for (1) the rare phenobarbital overdoses (as discussed above), (2) for the body packer or body stuffer (see below), and (3) for the patient suspected of taking a sustained release preparation. If the patient has difficulty tolerating activated charcoal because of

drug-induced vomiting, smaller doses of activated charcoal administered more frequently may reduce the likelihood of vomiting. It may, however, be necessary to give either IV metoclopramide (10 to 50 mg IVP) or ondansetron (4 to 8 mg IVP) to ensure satisfactory administration of charcoal.⁴⁹⁵

5. Guard against aspiration: Do not force patients who are nauseated to take activated charcoal. If nausea exists, treat with metoclopramide as above. Patients who do not have a gag reflex should have their airways protected with endotracheal intubation (although this does not guarantee protection) and elevation of the head of the bed to 45°.

6. Laboratory Data: Baseline laboratory data should be guided by clinical presentation. If the patient is asymptomatic no laboratory is immediately essential. Perform a CBC, and electrolytes with CPK isoenzymes if the patient is obtunded or has chest pain, to rule out occult metabolic/infectious disease and/or myocardial infarction. While the use of toxicology screens of blood and urine are generally overutilized,⁵ they are recommended if diagnosis remains questionable.

Comment: The use of urine toxicology screening may be particularly misleading in the case of a body packer or stuffer and should not be used to determine if the patient ingested any drugs. Recreational use of the drug prior to “stuffing” could lead to a false positive test. On the other hand, no prior drug usage without rupture of packets could lead to a false negative test. In one study of 50 body packers 64% had positive urine toxicology screens for drugs of abuse.⁵¹⁴

Secondary Interventions

1. The body stuffer: Some authors recommend that the asymptomatic body packer or stuffer should be observed for a period of at least 48 to 72 h and treated with repeated dose-activated charcoal and cathartics.⁴⁷⁹ This approach may be better suited to the treatment of body packers who have a lethal amount of drug in their intestinal tract. In the asymptomatic body stuffer the administration of activated charcoal and observation seems more appropriate but has not been carefully studied. In a series of more than 100 cocaine body packers, those who went on to develop serious complications became symptomatic within 6 h.⁵¹⁵ A recommended treatment approach follows:

- a. **Activated charcoal:** Give activated charcoal, 1 g/kg.
- b. **Observation:** If asymptomatic, observe for 6 h and repeat activated charcoal.
- c. **Discharge:** At this time it is felt that there is too little evidence to guide a well-supported recommendation for the release of these patients from the hospital. Clinical judgment should be used based on the type and the amount of drug ingested. Some recommend discharge after an observation period of greater than 6 h if the patient is asymptomatic.
- d. **WBI:** If symptomatic and large amount of drug has been ingested or sustained-release preparations are involved, consider whole bowel irrigation with 2 L/h of polyethylene glycol (PEG) after the first dose of activated charcoal.

2. The body packer: Treatment is as per the body stuffer and it is wise to admit these patients until all packets are passed and accounted for.

- a. **X-rays:** A plain upright abdominal film can detect a large percentage of packets (e.g., false negative rate of 17 to 19% in two series^{516,517}) and is recommended to determine location and amount of drug ingested. However, a negative x-ray does not rule out body packing.
- b. **WBI:** The use of electrolyte bowel preparation solutions such as polyethylene glycol (e.g., GO-LYTELY) has aided foreign body passage^{475,518} and is recommended in all cases except those involving heroin. Give 2 L/h for adults and 500 cc/h for children.
- c. **Cathartic:** An alternative to whole bowel irrigation is a cathartic, such as 3% sodium sulfate solution (250 to 500 ml), given orally with the activated charcoal. Cathartics such as sodium sulfate do not eliminate packets as rapidly as WBI. This may allow more time for the packets to dissolve. Conversely, a gentler approach with less risk of damage to the packets is provided. Use of cathartics

without WBI is recommended in uncooperative patients (unless a court order is obtained), those who body-pack heroin (due to the reported possibility of increasing solubility of heroin in polyethylene glycol⁵⁰⁷), and in those known to have packets that are weakly wrapped (due to theoretical concerns about breaking open packets with vigorous irrigation and increased peristalsis⁵⁰⁷). Further studies are needed to validate these recommendations.

- d. **Enemas:** If foreign bodies are located in the colon, low-volume phosphasoda enemas or high-volume normal saline enemas may be helpful.⁵⁰⁷
- e. **Suppository:** One Dulcolax suppository per rectum to empty the rectum.
- f. **Gastrointestinal series:** Following the passage of the “last” packet, a Gastrograffin upper gastrointestinal series with small bowel follow-through may be performed to ensure that the gut has been purged of all containers.⁵¹⁹
- g. **Surgery:** In the presence of a leaking or a ruptured package, decisions about surgical removal should be made on an individual basis; laparotomy is indicated if this is intestinal obstruction.

Comment: Because of risk of packet rupture avoid attempts to remove packages via gastroscopy or colonoscopy.⁵¹⁹ Syrup of ipecac or gastric lavage are ineffective due to the large size of the packets, and may cause packages to break.

3. Disposition: Patients may be discharged from the emergency department if they meet the following criteria:

- a. Normal vital signs
- b. Normal physical exam, including the presence of bowel sounds
- c. Normal or near normal laboratory data
- d. Ingestion known to be nontoxic
- e. Psychiatric referral
- f. Stable family environment

Comment: As noted previously more studies are needed to support any recommendations for the safe discharge of body stuffers.

8.2.10 Management of Specific Drugs of Abuse

8.2.10.1 Psychostimulants

Drug	Unique Characteristics	Key Management Issues
Cocaine	Stimulant associated with more serious complications than any other; affects all organ systems; no longer confined to affluent sectors of society	Adrenergic crisis, hyperthermia, hypertension, cardiac ischemia and arrhythmias, seizures, stroke, panic attacks, psychosis, rhabdomyolysis
Amphetamines and methamphetamine	Frequently associated with paranoid psychosis after chronic abuse Lead poisoning has been described (lead is used as a reagent in illicit laboratories)	Same as cocaine with lower incidence of cardiac ischemia, stroke
MDMA, MDEA/MDA (“Ecstasy”)	Designer amphetamine widely used at dance parties or “raves”; affects serotonin more than other amphetamines, leading to hallucinations; possibly linked to the serotonin syndrome	Same as cocaine with lower incidence of cardiac ischemia, stroke; severe hyperthermia in dehydrated dancers has led to death Rehydrate and control hyperthermia
Methcathinone (“CAT”)	Designer amphetamine with intoxicating effects that may last up to 6 days; more common in former Soviet Union	Same as amphetamines

Continued.

Drug	Unique Characteristics	Key Management Issues
Pemoline/methylphenidate	Principal therapeutic use is in children and adults with attention-deficit disorder; commonly associated with abnormal involuntary movements	Same as amphetamines
DOB	Strong hallucinogenic effects that are long-lasting (up to 10 h); may have an ergot-like effect	Same as amphetamines, severe hypertension, or evidence of ischemia (digital, mesenteric) should be treated with phentolamine and anticoagulation
TMA-2, DOM/STP	Designer amphetamines with less sympathetic stimulation in usual doses; prominent hallucinogenic effects	Adequate treatment is usually possible by calming hallucinations with benzodiazepines and removal to a quiet setting
Ephedrine	Recently removed from over-the-counter sale; amphetamine-like substance less potent than amphetamines	Same as amphetamines
Phenylpropanolamine	Primarily an β -adrenergic agonist, as a result hypertension with reflex bradycardia is common, also associated with cerebral hemorrhage	May treat hypertension with an β -blocker such as phentolamine; do not treat bradycardia with atropine since this will exacerbate hypertension
Mescaline	Phenylethylamine derivative found in peyote cactus, associated with strong hallucinogenic properties due to effects on the serotonergic system	Adequate treatment is usually possible by calming hallucinations with benzodiazepines and removal to a quiet setting
PCP, PHP, and derivatives	Associated with erratic, violent behavior; intoxicated patients prone to sustaining significant injuries due to dissociative, anesthetic properties	As with other psychostimulants with greater emphasis on controlling behavioral toxicity since this is the major cause of death

Abbreviations: MDMA-3,4-methylenedioxyamphetamine; MDEA-3,4-methylenedioxyamphetamine; MDA-3,4-methylenedioxyamphetamine; DOB-4-bromo-2,5-dimethoxyamphetamine; TMP-2-2,4,5-trimethoxyamphetamine; DOM/STP-4-methyl-2,5-dimethoxyamphetamine; PCP-Phencyclidine; PHP-phenylcyclohexylpyrrolidine.

Contraindications: Nonselective beta-blockers should not be administered to patients with chest pain if a psychostimulant has been ingested although cardioselective beta-blockers may be used for certain tachyarrhythmias. Acidification of urine may slightly hasten the elimination of PCP and amphetamines but it is not recommended due to an increased risk of myoglobinuric renal failure.

8.2.10.2 Opiates

Drug	Unique Characteristics	Key Management Issues
Diacetylmorphine (heroin)	Prototype opiate of abuse, rapidly metabolized to morphine, more lipid soluble	Respiratory depression, coma, anoxic encephalopathy, pulmonary edema, withdrawal, compartment syndromes
Methadone (Dolophine)	Slow onset and long duration of action (half-life 15–72 h)	As with heroin; may require a naloxone infusion (see below) and prolonged monitoring
Designer Opiates: Fentanyl (Sublimaze), Sufentanil (Sufenta), Alfentanil (Alfenta)	Most potent opiates (16–700 \times morphine), with rapid onset and short duration of action (minutes)	As with heroin May accumulate in body fat necessitating observation periods similar to heroin overdose (12 h); may see negative screen for opiates

Continued.

Drug	Unique Characteristics	Key Management Issues
Propoxyphene (Darvon)	High mortality, sudden death reported, convulsions and cardiac arrhythmias due to metabolite (norpropoxyphene), fat soluble so may have prolonged duration of action	As with heroin Prolonged observation required after overdose (see Table 8.2.1) Wide complex tachycardia may respond to bicarbonate, may be resistant to naloxone, check acetaminophen level
Pentazocine (Talwin)	Agonist-antagonist, dysphoria, no cases of pulmonary edema reported	As with heroin May be resistant to naloxone
Dextromethorphan/ codeine	Less respiratory depression, possible serotonin-releasing effects	As with heroin Usually less serious in overdose than other opiates, check acetaminophen level if codeine ingested
Meperidine (Demerol)	Synthetic opiate associated with seizures in large doses due to metabolite (normeperidine)	As with heroin
Hydromorphone (Dilaudid)	Similar to morphine but more potent and shorter duration of action	As with heroin
Morphine (MS-contin)	Sustained-release, oral chewing converts to rapidly acting agents	As with heroin Prolonged observation required after overdose (see Table 8.2.1)

Contraindications: Administration of high dose (>2.0 mg) naloxone in any patient at risk for opiate withdrawal.

Naloxone infusion: Take two-thirds the amount of naloxone required for the patient to initially wake up and give that amount at an hourly rate. Mix the naloxone in the patient's maintenance IV (D5W, D51/2NS, 1/2NS, NS, etc.). Infusions should be maintained in an intensive care setting. Patients should be closely watched any time the infusion is stopped. Duration of observation depends on the route of drug administration, the drug ingested, the presence or absence of liver dysfunction, and the possibility of ongoing drug absorption from the gastrointestinal tract. Usually 6 h is adequate.

8.2.10.3 Sedative–Hypnotic Agents

Drug	Unique Characteristics	Key Management Issues
Benzodiazepines	High therapeutic index makes death unlikely unless coingestions involved; memory impairment common	Respiratory depression, coma, compartment syndromes; severe withdrawal; use flumazenil in selected cases only; supportive care usually all that is required
GHB	Common at “raves,” associated with profound coma that rapidly resolves within 2 h, increased muscle tone with jerking	Supportive care, rarely requires endotracheal intubation, guard against aspiration
Long-lasting barbiturates (i.e., phenobarbital); duration of action = 10–12 h	Phenobarbital ($t_{1/2}$ = 24–140 h) may induce prolonged deep coma (5–7 days) mimicking death; pneumonia is a common complication due to prolonged coma; hypothermia	As with benzodiazepines, although cardiac depression and hypotension are more common and may necessitate cardiac support; alkalization of urine may increase elimination; MDAC in selected cases (see discussion); hemoperfusion in selected cases
Other barbiturates: Intermediate acting (i.e., amobarbital) Short acting (i.e., secobarbital) Ultrashort acting (i.e., thiopental)	Commonly abused barbiturates; chronic drowsiness, psychomotor retardation; hypothermia	As above, although alkalization, MDAC not helpful; hemoperfusion in selected cases; major withdrawal may necessitate hospitalization

Continued.

Drug	Unique Characteristics	Key Management Issues
Ethchlorvynol (Placidyl)	Pungent odor sometimes described as pearlike, gastric fluid often has a pink or green color, noncardiac pulmonary edema	See barbiturates
Glutethimide (Doriden)	Prominent anticholinergic side effects including mydriasis Prolonged cyclic or fluctuating coma (average 36–38 h); often mixed with codeine as a heroin substitute	See barbiturates
Meprobamate (Miltown)	Forms concretions, hypotension is more common than with other sedative-hypnotics, prolonged coma (average 38–40 h)	If concretions suspected, WBI or gastroscopic or surgical removal of drug may be necessary; hemoperfusion useful in severe cases
Methqualone (Quaalude)	Muscular hypertonicity, clonus, and hyperpyrexia, popular as an “aphrodisiac” or “cocaine downer”; no longer manufactured in the U.S.	Charcoal hemoperfusion increases clearance and may be useful in severe cases; diazepam may be necessary to treat severe muscular hypertonicity or “seizures”
Chloral hydrate	Metabolized to trichloroethanol which may sensitize the myocardium to the effects of catecholamines, resulting in cardiac arrhythmias	Tachyarrhythmias may respond to propranolol, 1–2 mg IV or esmolol; flumazenil has been reported to produce dramatic reversal of coma in one case; amenable to hemodialysis

Note: Catecholamines (especially dopamine and epinephrine) are relatively contraindicated in cases of chloral hydrate-induced tachyarrhythmias.

Abbreviations: GHB, gammahydroxybuterate; MDAC, multiple-dose activated charcoal; WBI, whole bowel irrigation.

8.2.10.4 Hallucinogens

Drug	Unique Characteristics	Key Management Issues
LSD	Potent agent associated with panic attacks, acute psychotic reaction, and flashbacks in chronic users; vital signs are usually relatively normal; hallucinations for 1–8 h	Patients usually respond to benzodiazepines and seclusion in a quiet environment; toxicology screen negative; in extremely agitated patients watch for hyperthermia, rhabdomyolysis
Marijuana	Commonly used, associated with conjunctival injection, stimulation of appetite, orthostatic hypotension, and mild tachycardia; duration of effect: 3 h	Usually respond to simple reassurance and possible adjunctive benzodiazepine
Ketamine	Dissociative anesthetic with hallucinations characterized by profound analgesia, amnesia, and catalepsy Increasingly common as drug of abuse; duration of effect: 1–3 hours	Provide supportive care until drug effects wear off; cardiovascular parameters are usually well preserved
Atropine, hycosyamine, scopolamine (<i>Datura stramonium</i> or Jimson weed)	Anticholinergic syndrome with true delirium, symptoms may continue for 24–48 h because of delayed GI motility	Usually supportive care only, consider activated charcoal; physostigmine for uncontrolled agitation, hyperthermia

Continued.

Drug	Unique Characteristics	Key Management Issues
Solvents	Products of petroleum distillation abused by spraying them into a plastic bag or soaking a cloth and then deeply inhaling; cardiac sensitization may result in malignant arrhythmias, low viscosity agents (i.e., gasoline) are associated with aspiration; chronic exposure associated with hepatitis and renal failure	Usually hallucinogenic effects are short lived; removing the patient from the offending agent and providing fresh air are all that is necessary; treat aspiration by supporting airway; arrhythmias may respond to beta-blockers, epinephrine may worsen arrhythmias
Psilocybin	From the <i>Stropharia</i> and <i>Conocybe</i> mushrooms; suppresses serotonergic neurons, less potent than LSD with hallucinations that last from 2–8 h, patients may exhibit destructive behavior; hallucinations for 1–6 h	As with LSD

Note: Epinephrine is contraindicated in cases of solvent-induced tachyarrhythmias.

Abbreviations: LSD, lysergic acid diethylamide, GI, gastrointestinal.

Doping contravenes the ethics of both sport and medical science. It consists of the administration of substances belonging to prohibited classes of pharmacological agents, and/or the use of various prohibited methods.

WADA — IOC Definition, 2004

Doping is not a new phenomenon. Ancient Greek athletes tried to enhance performance by ingestion of alcoholic drinks and sheep testicles. The term “doping” is said to have its roots in the Dutch word *Dop*, which, in South Africa, referred to an alcoholic drink used as a stimulant by the Zulus in ceremonial dancing. At the end of 19th century, athletes experimented with cocaine, heroin, and strychnine. In the 1904, Thomas Hicks nearly died using strychnine in combination with brandy during a bicycle race. Today modern drugs have replaced alcohol as doping agent, although strychnine is still rarely reported. These examples illustrate that misuse of drugs by athletes has been a problem since the beginning of sports history. About 35 years ago, after the first widely reported doping scandals, health and sports ethics became a major concern of the medical commission of the International Olympic Commission (IOC) and also of the individual sport federations. Doping has also become a problem even in recreational sports. Thus, the fight against doping began.

The medical commission of the IOC has created a list of forbidden substances and prohibited methods, which is included in the IOC's medical code. Doping control is performed by a network of IOC accredited laboratories, which analyze urine samples collected after or out of competition. Following the World Anti-Doping Conference in Lausanne in 1999, sports authorities and governments decided to produce a World anti-doping code (Code) and to fund a World Anti-Doping Agency (WADA). The main aim of WADA is to harmonize the fight against doping around the world. The anti-doping Code works in conjunction with four International Standards aimed at harmonization among anti-doping organizations:

1. Prohibited List of substances and methods
2. International standards for testing
3. International standards for laboratories
4. Therapeutic use exemptions (TUES)

These standards have been the subject of lengthy consultation among the WADA stakeholders and are mandatory for all signatories of the World Anti-Doping Code.

Prohibited List of Substances and Methods

The Prohibited List (List) was first published in 1963 under the leadership of the International Olympic Committee. Since 2004, it had been updated and published by the WADA. The List is the cornerstone of the Code and a key component of harmonization. It lists substances and methods prohibited in and out of competition, as well as substances prohibited for particular disciplines. The use of prohibited substances can be authorized for medical reasons by virtue of a TUES.

Prohibited Substance Classes:

1. S1. Anabolic Agents
Anabolic Androgenic Steroids (AAS), e.g., testosterone, nandrolone, methandienone, stanozolol, etc.
Other anabolic agents, e.g., Clenbuterol
2. S2. Hormones and related substances
Erythropoietin (EPO)
Growth hormone (GH), insulin-like growth factor (IGF-1), mechano growth factors (MGFs)
Gonadotrophins (LH, HCG)
Insulin
Corticotrophins
3. S3. Beta-2-agonists
4. S4. Agents with anti-estrogenic activity
Aromatase inhibitors, including anastrozole, letrozole, etc.
Selective estrogen receptor modulators (SERMs), including tamoxifène, toremifene, etc.
Other anti-estrogenic substances, including clomiphene, cyclofenyl, etc.
5. S5. Diuretics and other masking agents
Masking agents, including epitestosterone, probenecid, plasma expanders
Diuretics, including acetazolamide, furosemide, etc.
6. S6. Stimulants
Examples: Amphetamine, ethylefrine, modafinil, ephedrine, cathine, methylephedrine, etc.
Note: For ephedrine, methylephedrine, and cathine a cutoff urine concentration has been defined
7. S7. Narcotics
Examples: Buprenorphine, fentanyl, methadone, etc.
8. S8. Cannabinoids
9. S9. Glucocorticoids
10. P1. Alcohol and P2. Beta-blockers are prohibited in some specific sports

Table 9.1 General Statistics for 2004

Sports	Samples Analyzed	Adverse Analytical Findings	% Adverse of Total
Olympic	128,591	2,145	1.67
Non-Olympic	40,596	764	1.88
Total	169,187	2,909	1.72

Table 9.2 Number of Substances Identified for 2004

Substance Group	No.	% of All Adverse Analytical Findings
Anabolic agents	1191	36.0
Glucocorticoids	548	16.6
Cannabinoids	518	15.7
Stimulants	382	11.6
beta-2-Agonists	381	11.5
Masking agents	157	4.8
Peptide hormones	78	2.4
beta-Blockers	25	0.8
Narcotics	15	0.5
Anti-Estrogens	8	0.2
Blood transfusion	2	0.1
Total	3305	

Prohibited Methods:

1. M1. Enhancement of oxygen transfer
Blood doping, for example, homologous or autologous blood transfusion
Artificial transport of oxygen, for example, PFCs, modified hemoglobins, etc.
2. M2. Chemical and physical manipulation
Tampering with the sample
Intravenous infusions
3. M3. Gene doping

International Standards for Testing

The purpose of the International Standards for Testing is to plan for effective testing and to maintain the integrity and identity of samples throughout the testing process, from notifying the athlete to transport of the samples for analysis.

International Standard for Laboratories

The purpose of the International Standard for Laboratories (ISL) is to ensure production of valid test results and evidentiary data, and to achieve uniform and harmonized results and reporting from all accredited laboratories. The ISL includes requirements for WADA accreditation of doping laboratories, operating standards for laboratory performance, and description of the accreditation process.

WADA publishes annually an overview of the results reported by its accredited laboratories.¹ The 2004 statistics include analyses conducted by WADA-accredited laboratories for in- and out-of-competition testing (Table 9.1 through Table 9.3). When looking at the statistics of 2004, anabolic steroids are still the most often reported doping agents, as it has been the case every year since the beginning of the 1990s. Surprisingly, the glucocorticoids and cannabinoids are nowadays at second and third place. The large number of testosterone cases should be taken with caution

Table 9.3 The 12 Most Identified Substances for 2004

	Substance	Group	No.
1	Cannabis	Cannabinoids	518
2	Testosterone ^a	Anabolic steroids	392
3	Nandrolone	Anabolic steroids	339
4	Salbutamol ^b	beta-2-Agonists	251
5	Triamcinolone Ac. ^b	Glucocorticoids	246
6	Stanozolol	Anabolic steroids	226
7	Betamethasone ^b	Glucocorticoids	121
8	Amphetamine	Stimulants	112
9	Ephedrine	Stimulants	102
10	Terbutaline ^b	beta-2-Agonists	78
11	Cocaine	Stimulants	75
12	Methandienone	Anabolic steroids	62

^a These are adverse analytical findings reported from laboratories. Some of these results can be due to naturally elevated testosterone levels.

^b beta-2-Agonist and glucocorticoid adverse analytical findings could have been justified by therapeutic use exemption (TUE).

because the differentiation between a naturally elevated concentration of the endogenous hormone and abuse of testosterone esters cannot always be done.

International Standard for Therapeutic Use Exemptions

The purpose of the International Standard for TUE is to ensure that the process of granting TUEs is harmonized across sports and countries. But what is a TUE? Athletes, like all others, may have illnesses or conditions that require them to take particular medications. If the medication happens to fall under the Prohibited List, a TUE authorizes the athlete to take the needed drug.

The criteria to grant a TUE are:

The athlete would experience significant health problems without taking the prohibited substance or method

The therapeutic use of the substance would not produce significant enhancement of performance

There is no reasonable therapeutic alternative to the use of the prohibited substance or method.

Under the World Anti-Doping Code, WADA has issued an International Standard for the granting of TUEs. The standard states that all International Federations and National Anti-Doping Organizations must have a process in place whereby athletes with documented medical conditions can request a TUE. A panel of independent physicians called the Therapeutic Use Exemption Committee (TUEC) examines the request. International Federations and National Anti-Doping Organizations are responsible for granting or declining such applications. There are two types of TUEs: abbreviated and standard.

Abbreviated TUE: Only for glucocorticosteroids by nonsystemic routes (topical application) and beta-2 agonists (formoterol, salbutamol, salmeterol, and terbutaline) by inhalation. Dermatological applications are not prohibited and do not require any TUE. A notification is sent to the athlete by the relevant organization upon receipt of a duly completed request. The athlete can begin treatment as soon as the form has been received by the relevant organization.

Standard TUE: For any treatment involving a substance or a method on the Prohibited List that does not qualify for an abbreviated TUE, the prescription must be reviewed by a TUEC. If approved, the athlete may begin treatment only after receiving the authorization notice from the relevant organization (except in rare cases of an acute life-threatening condition for which a retroactive approval may be considered).

9.1 TESTOSTERONE AND SYNTHETIC ANABOLIC STEROIDS

Christophe Saudan, Ph.D. and Norbert Baume, Ph.D.

Swiss Laboratory for Doping Analyses, University Institute of Legal Medicine, Lausanne, Switzerland

9.1.1 Introduction

Anabolic steroids are synthetic derivatives of testosterone modified to enhance the anabolic rather than the androgenic actions of the hormone. Testosterone is hormone-synthesized in the human body from cholesterol. It serves distinct functions at different stages of life. During embryonic life, androgen action is central to the development of the male phenotype. At puberty, the hormone is responsible for the secondary sexual characteristics that transform boys into men. Testosterone intervenes in many physiological processes in the adult male including muscle protein metabolism, sexual and cognitive functions, erythropoiesis, plasma lipids, and bone metabolism (Figure 9.1.1).

9.1.2 Pharmaceutical Action of Anabolic Steroids

Testosterone is virtually inactive when taken orally. After oral ingestion, testosterone is absorbed from the small intestine and passes via the portal vein to the liver where it is rapidly metabolized, mostly to inactive compounds. Accordingly, chemical modifications of testosterone have been made to alter the relative anabolic–androgenic potency, slow the rate of inactivation, and change the pattern of metabolism. Most orally anabolic-androgenic steroids (AAS) preparations are 17- β alkylated derivatives of testosterone that are relatively resistant to hepatic inactivation. Esterification of the 17- β hydroxyl group makes the molecule more soluble in lipid vesicles for injection. This slows the release of the injected steroid into the circulation. Commonly used 17- β alkyl and 17- β ester derivatives are:

17- β alkyl derivatives: Stanozolol, danazol, fluoxymesterone, methyltestosterone, methandrostenolone, oxandrolone, and oxymetholone

17- β ester derivatives: Nandrolone decanoate, boldenone, trenbolone, methenolone, and testosterone enanthate

Evidence suggests that with normal male physiological plasma levels of testosterone, the androgen receptors, to which testosterone and dihydrotestosterone (DHT, an active metabolite of testosterone) bind, are fully saturated. *In vitro* studies have demonstrated that the dose–response relationship of testosterone and skeletal muscle growth reaches a plateau once the physiological concentration is exceeded. It has been suggested that when anabolic steroids are abused by athletes, the drugs exert their effects by another receptor mechanism that is unsaturated or unaffected by normal plasma

Figure 9.1.1 Molecular structure of testosterone.

testosterone and DHT levels. Indeed, it is believed that the effects of supraphysiological doses of testosterone on muscle are mediated through an antiglucocorticoid action, independent of the androgen receptor. Glucocorticoids such as cortisol and corticosterone are hormones that influence glucose synthesis and protein catabolism. Stimulation of glucocorticoid receptor will lead to an enhancement of protein breakdown in muscle. According to one theory the high doses of anabolic steroids used by many athletes displace glucocorticoids from glucocorticoid receptor and inhibit muscle protein catabolism, leading overall to an anabolic or muscle-building effect.²

9.1.3 Therapeutic Uses

A number of clinical studies using a variety of experimental designs have shown that the potent anabolic effects of AAS have a positive effect on various pathological conditions.³ Physiologic replacement doses of testosterone have been used to stimulate sexual development in cases of delayed puberty, and to substitute for the hormone after surgical removal of a testis. The first major clinical use of anabolic steroids was to inhibit the loss of protein and aid muscle regeneration after major surgery. Anabolic steroids may also be used to increase growth in prepubertal boys who have failed to reach their expected minimal height for their age.

9.1.4 Athletic Use

For many years, the medical community fought AAS use by denying that they had any effects on the lean body mass. Early studies were flawed and did not reflect the way AAS are actually used. Athletes “cycle” on and off compounds, switching from one to another to avoid developing tolerance. They “stack” AAS, taking several different steroids at the same time to lower the dose of each, and to activate different steroid receptors. The scientific basis for stacking is, however, highly questionable and has not been proved.

AAS are generally accepted as having the desired anabolic effects, provided athletes also have an adequate protein supply and exercise intensely. In a randomized controlled trial, those taking 600 mg testosterone intramuscular injections weekly for 10 weeks had significantly increased muscle mass, muscle strength, and fat-free mass compared to those taking a placebo. However, not all studies have found such strength gains.

9.1.5 Anabolic Testing

The latest list of prohibited substances, established by the WADA for 2005, includes two types of steroids: (1) typically exogenous steroids, main examples of which have been given previously, and (2) typically endogenous steroids, e.g., androstenediol, androstendione, dehydroepiandrosterone (DHEA), dihydrotestosterone (DHT), testosterone, and related substances.

Testing for anabolic agents in the urine of athletes was first implemented on a large scale during the 1976 Montreal Olympic Games. Testing was mainly based on radioimmunoassay (RIA) techniques. The techniques for the identification and characterization of steroids and their metabolites in urine have improved considerably during the last three decades. This improvement is largely due to the use of gas chromatography-mass spectrometry (GC-MS) techniques. Today, most anti-doping laboratories use techniques that are based on the solid-phase extraction of the urine sample, followed by chemical modifications prior to GC-MS analysis.⁴ The confirmation procedure for the unequivocal identification of an anabolic doping agent consists in matching GC and MS data of the supposed substance and/or its metabolites with pure standards, or matching the metabolite profile of the sample with reference urine originating from an excretion study.

The detection of exogenous substances requires the identification of a parent compound and/or at least one metabolite. However, with endogenously produced substances, such as

testosterone, the presence of the substance alone cannot be considered as an offense. Moreover, a cutoff value for testosterone concentration cannot be used because of large inter-individual and intra-individual urinary concentrations of the hormone.⁵ However, the intake of testosterone causes characteristic changes in the pattern of steroids excreted in the urine. In 1983, based on studies performed on athletes, the IOC adopted a ratio of testosterone to epitestosterone (T/E) of up to 6.0, as a criterion for the administration of testosterone. Epitestosterone formation seems to parallel testosterone formation,⁶ but it does not increase to the same extent as testosterone after exogenous testosterone administration, resulting in an increase of the T/E ratio.

In populations of athletes, a mean T/E ratio of less than 2.0 is observed. For that reason the IOC rules clearly state that a T/E ratio greater than 6.0 constitutes an offense, unless there is evidence that the result is due to an extraordinary physiological or pathological condition (e.g., low epitestosterone excretion, androgen producing tumor, and enzyme deficiencies). Before a sample is declared positive, further investigations are conducted as a confirmational study.⁷ As a first step, a comparison with previous values is made. After that, or if no previous values are available, several additional urine samples are analyzed over a short period. This longitudinal study may represent a useful tool to detect false-positive results (naturally elevated T/E ratios).

WADA suggested in 2004 that urine samples should now be submitted to isotopic ratio mass spectrometry (IRMS) if the T/E is greater than or equal to 4.0, and testosterone, testosterone metabolites, epitestosterone, and DHEA concentrations are greater than fixed cutoff concentrations.⁸ Even if additional studies of the particular athlete suggest the potential steroid profile manipulation, there is a lack of definitive proof for the exogenous application of natural steroids. This problem can be solved by the determination of the ratio of the two stable carbon isotopes $^{13}\text{C}/^{12}\text{C}$, which allow the differentiation of natural and synthetic steroids. As exogenous testosterone or precursors contain less ^{13}C than their endogenous homologues, a lower urinary $^{13}\text{C}/^{12}\text{C}$ ratio can be expected if steroids have been administered.

The method for determining the isotopic composition of the relevant analyte includes GS, a subsequent combustion to CO_2 , and, finally, MS analysis of the gas in a special multicollector mass spectrometer (isotope-ratio-mass-spectrometry, IRMS). The $^{13}\text{C}/^{12}\text{C}$ ratio of testosterone or its metabolites is measured and compared to urinary reference steroids within the sample.⁹ It should be emphasized that the $^{13}\text{C}/^{12}\text{C}$ ratio of these endogenous reference compounds should not be affected by steroid administration.¹⁰ The result will be reported as consistent with the administration of a steroid, if a significant difference is observed between the $^{13}\text{C}/^{12}\text{C}$ values of testosterone metabolites and the endogenous reference compound. According to population studies, the WADA Laboratory Committee has stated a difference cutoff for positivity in 2004. If the IRMS study does not clearly indicate exogenous administration, an inconclusive result may be reported and further longitudinal studies can be performed.⁸

Nandrolone, or 19-nortestosterone, is a synthetic AAS, a member of the norsteroids family derived from the testosterone molecule. A small chemical modification (on the carbon atom 19) gives nandrolone more anabolic rather than androgenic properties. Some nandrolone-positive cases with low levels of metabolites (19-norandrosterone and 19-noretiocholanolone) are encountered in several sports such as football, judo, and tennis. A debate about the capability of the human body to endogenously produce traces of nandrolone metabolites, without any intake of forbidden substances, was initiated a decade ago. Research projects on the effects of nandrolone and on its metabolism were performed and provided the following results:

Endogenous production of nandrolone has been observed. It is due to enzymatic transformation of endogenous testosterone to endogenous 19-nortestosterone (nandrolone).¹¹

A possible exogenous source is the intake of nutritional supplements and/or over-the-counter drugs, which have previously been intentionally or accidentally contaminated by nandrolone precursors.¹²⁻¹⁴

Physical exercise may also influence the excretion of nandrolone, but studies on this subject have produced mixed results.¹⁵⁻¹⁸

9.2 STIMULANTS

Lidia Avois-Mateus, Ph.D.

Swiss Laboratory for Doping Analyses, University Institute of Legal Medicine, Lausanne, Switzerland

9.2.1 Introduction

These drugs stimulate the central nervous system (CNS) and may be used to reduce fatigue, as well as increase alertness, competitiveness, and aggression. They are considered to have a performance-enhancing effect in explosive power activities and endurance events, since the capacity to exercise strenuously is increased and sensitivity to pain is reduced. Because of their short half-life, stimulants are mostly used on the day of a competition. They may also be used in training, to allow an increase in intensity of the training session. Testing for stimulants is done in-competition only. Because stimulants can increase an athlete's aggression toward other competitors or officials, their misuse in contact sports may be dangerous. Relatively high doses are needed to reduce fatigue, and performance may be reduced by side effects such as tremor.

The stimulant class includes psychomotor stimulants, sympathomimetics, and miscellaneous CNS stimulants.^{19,20} Specific examples of this class include caffeine, amphetamines, ephedrines, and cocaine (Figure 9.2.1).

9.2.2 Caffeine

Caffeine is the pharmacologically active substance found in tea, coffee, and cola. The amount of caffeine present varies according to the type of drink and the way it has been prepared. In addition, caffeine may be an ingredient of some common medications (e.g., against the common cold, pain relievers), but usually in quantities of less than 100 mg per dose. Caffeine produces mild CNS stimulation, similar to that of amphetamines, reducing fatigue and increasing concentration and alertness. Physiological effects include increased cardiac output, and increased metabolic rate and urine production. High doses can cause anxiety, insomnia, and nervousness.²⁰ Since 2004, caffeine has been removed from the list of prohibited substances and included, instead, in the Monitoring Program. The Monitoring Program is concerned with substances that are not on the Prohibited List, but which WADA wishes to monitor in order to detect patterns of misuse in sport (WADA Code 4.5).

Figure 9.2.1 Common stimulants.

9.2.3 Amphetamine

Amphetamine was synthesized in 1920 and used to reduce fatigue and increase alertness in soldiers during World War II. Many derivatives have since been elaborated, such as methamphetamine, dimethamphetamine, methylenedioxyamphetamine (MDA), methylenedioxymethamphetamine (MDMA, “ecstasy”), selegiline, etc. They are all forbidden in the practice of sport. Amphetamine was used as a nasal decongestant, antidepressant, and appetite suppressant, but its powerful CNS stimulant properties were soon discovered. It acts primarily by enhancing the brain activity of norepinephrine and dopamine, resulting in intensification of alertness, concentration, and self-confidence. Amphetamines may induce dependence, and generally fall under the drug legislation of the athlete’s own country.

9.2.3.1 Metabolism of Amphetamines

Amphetamine is readily absorbed, mainly from the small intestine, and the peak concentration occurs 1 to 2 h following administration. Absorption is usually complete in 2.5 to 4 h and is accelerated by food intake. The metabolism of amphetamine has been difficult to investigate because of the wide variation between species in its metabolic effects. The principal amphetamine metabolites are *p*-hydroxyephedrine and *p*-hydroxyamphetamine. Amphetamine is eliminated by renal filtration. For the detection of amphetamine use in sport, the urine is analyzed for the parent compound amphetamine. After a single dose of amphetamine, it can be found in the first void urine and continues to be detectable for at least 48 h after the intake of the drug. The peak urine concentration is quite variable and occurs between 3 and 12 h after the intake of the drug. Amphetamine excretion may be accelerated by acidification of the urine — this property has been used in the treatment of amphetamine overdose.

9.2.3.2 Amphetamine Action

Amphetamine’s positive effects include an increase in physical energy and an improvement in some mental skills, but there are also increased talkativeness, restlessness, and excitement. Subjects taking amphetamine also report that they feel confident, efficient, ambitious, and that their food intake is reduced. Other negative effects of amphetamine — which can be dose-dependent — are anxiety, indifference, slowness in reasoning, irresponsible behavior, irritability, dry mouth, tremors, insomnia, and, following withdrawal, depression.

Tolerance develops rapidly to many of the effects of the amphetamines. Amphetamines induce dependence and the amphetamine-dependent person may become psychotic, aggressive, and anti-social. Withdrawal of amphetamines is associated with mental and physical depression. Other major side effects of amphetamine administration include confusion, delirium, sweating, palpitations, mydriasis, tachypnea, hypertension, tachycardia, tremors, as well as muscle and joint pain. Chronic amphetamine administration is also associated with myocardial pathology and possibly with growth retardation in adolescents. High chronic doses may lead to a variety of persistent personality changes, paranoid delusions, and tactile hallucinations called *amphetamine psychosis*. Transient changes indistinguishable from schizophrenia were commonly reported during the 1950s, when amphetamine abuse was very widespread.

9.2.3.3 Amphetamine in Sport

The action of amphetamine on sporting performance was first investigated in 1959 and it has been concluded that it enhances anaerobic performances while having little or no effect on aerobic activity. Since then, amphetamine has been studied in attempts to enhance performance in various disciplines. It might improve reaction time when fatigued, increase muscular strength and endur-

ance, increase acceleration, increase lactic acid level at maximal exercise, increase anaerobic endurance capacity, and stimulate metabolism with loss of body fat. Dosage seems to be important depending on the desired effect. Aggressiveness increases with high dosage, whereas alertness is enhanced with lower quantities.

All amphetamines are banned by the WADA and IOC codes. No quantification is necessary, as the qualitative demonstration of the substance is sufficient to declare the case an analytical adverse finding. The presence of amphetamine in urine is considered a severe doping offense, because amphetamine has no medical indication any more and its use is prohibited in many countries.

9.2.4 Cocaine

Cocaine is the most potent stimulant of natural origin. Unlike amphetamines, which are synthetic compounds, cocaine is obtained from naturally occurring *Coca* species, although it can be produced synthetically. Its current notoriety belies the fact that people have used the drug as a stimulant for thousands of years. In the past cocaine was used in a number of patent medicines and even in soft drinks. Except for head and neck surgery, where it is still used as a local anesthetic (because it is a vasoconstrictor in addition to being an anesthetic), its therapeutic indications are now mostly obsolete, as much safer drugs have been produced. Cocaine can be snorted, smoked, or injected.

9.2.4.1 Cocaine's Actions

Physical effects of cocaine use include vasoconstriction, thermogenesis, increased heart rate, and increased blood pressure. Cocaine also increases motor activity, talkativeness, and is a potent euphoriant. Users feel an initial “rush” or sense of well-being, of having more energy, and of being more alert. The duration of cocaine’s immediate euphoric effects, which include hyperstimulation, reduced fatigue, and increased mental clarity, depends on the route of administration, but generally is very short.

9.2.4.2 Cocaine in Sport

Despite popular myth, cocaine does not really enhance performance whether at work, in sports, at school, or with sex. On the contrary, long-term use can lead to loss of concentration, irritability, loss of memory, paranoia, loss of energy, anxiety, and a loss of interest in sex. Several studies have demonstrated that cocaine has no beneficial effect on running times and reduces endurance performance. Furthermore, at all doses, cocaine significantly increases glycogen utilization and plasma lactate concentration, without producing consistent changes in plasma catecholamine levels.

The controlling effect cocaine has on an addict’s life can lead to exclusion of all other facets of life. Nevertheless, despite these apparently detrimental effects, cocaine continues to be abused in sport. The reason may be that cocaine has positive ergogenic effect on activities of short duration requiring a burst of high-intensity energy output. The activities associated with the drug’s CNS stimulatory effect may be more important than its action on peripheral metabolism. It has been suggested that it is precisely because of central heightened arousal and increased alertness, achieved principally at low doses, that cocaine is used in sport.

Cocaine can currently be administered by a doctor for legitimate medical uses, such as local anesthetic for some eye, ear, and throat surgeries. Both WADA and IOC ban cocaine, including its use as a local anesthetic. A recent report showed positive urine test results for benzoylecgonine (metabolite of cocaine) within 24 h in subjects after ingestion of a 250 ml infusion of Mate de Coca tea.²¹ Cocaine, like amphetamine, is part of the category S6 of the prohibited substances in competition and its — and/or its metabolites — presence in urine can be considered a severe doping offense.

9.2.5 Ephedrine

Ephedra alkaloids, which are popular components of many nutritional supplements, are naturally occurring CNS stimulants, which may be obtained from several *Ephedra* plant species. Naturally occurring *Ephedra* plants contain ephedrine, pseudoephedrine, norephedrine, methylephedrine, norpseudoephedrine, and methylpseudoephedrine. Phenylpropanolamine is a synthetic compound with effects similar to ephedra-alkaloids. Methylephedrine is a very widely used cough suppressant, popular in Asia. Historically, ephedra-alkaloids have been used for both asthma and allergies in China for more than 5000 years. The structure of ephedrine is closely related to methamphetamine, although its effects on the CNS are much less potent and longer acting than those of the amphetamines. Its peripheral stimulant actions are similar to but less powerful than those of epinephrine (also called adrenaline), a hormone produced in the body by the adrenal glands.

9.2.5.1 Ephedrine Action

Ephedrine is a mixed sympathomimetic agent that acts as a stimulant in the CNS by enhancing the release of norepinephrine from sympathetic neurons and stimulating alpha- and beta-receptors. Ephedrine is the most potent thermogenic agent of the ephedra alkaloids. It increases heart rate, but only by an average of 8 to 10 beats per minute, and thereby cardiac output. In multiple controlled studies it has been found to cause minimal effect on systolic pressure and no effect or even a decrease in diastolic pressure (the phenomenon known as diastolic runoff). When given as an intravenous bolus it causes peripheral vasoconstriction resulting in an increase of peripheral resistance that may lead to a sustained rise in blood pressure, which is why it is still very widely used to counter the hypotensive effects of spinal anesthesia. Ephedrine relaxes bronchial smooth muscle and is used as a decongestant and for temporary relief of shortness of breath caused by asthma, although it quickly loses its effect because of beta-receptor downregulation. It is present in numerous nutritional and dietary supplements, such as energy stimulants and anorexic agents, although its use in the U.S. has now been banned. Pseudoephedrine can be found in many over-the-counter preparations for respiratory infections or allergies. Phenylpropanolamine, similarly to pseudoephedrine, has still been used recently in over-the-counter diet pills. Ephedrine is excreted largely unchanged in the urine and the usual elimination half-life is 3 to 6 h, which can be prolonged with increased urine pH.

9.2.5.2 Ephedrine in Sport

With their stimulant properties and sympathomimetic actions, ephedra-alkaloids have been perceived as potential performance-enhancing substances, offering unfair advantages to athletes, even if used in supplement forms.²² It appears, through various studies, that the isolated use of ephedrine, pseudoephedrine, and phenylpropanolamine at the usual dosages has an inconsistent, and probably insignificant, ergogenic benefit for power, endurance, strength, or speed. Other studies looking at the use of ephedrine combined with vitamins, minerals, or caffeine have, nevertheless, supported potential ergogenic effects. Many athletes indeed use food supplements containing ephedra alkaloids because of supposed energy increase and potential increase of metabolism with fat loss and increased muscular strength. A number of placebo-controlled studies have evaluated the effects of ephedrine in combination with caffeine. They demonstrated a prolonged time until exhaustion and a decreased perception of exhaustion on cycle ergometry.

WADA and IOC tolerate the medical use of ephedrine at therapeutic levels. Nevertheless, an ephedrine urine concentration of higher than 10 µg/ml is considered as positive result. Unlike amphetamine and cocaine, even if ephedrine is part of the category S6 of the prohibited substances in competition, its presence in urine is not considered as a severe doping offense and the sanctions are often milder or submitted to discussion.

9.3 ERYTHROPOIETIN — BLOOD DOPING

Neil Robinson, Ph.D.

Swiss Laboratory for Doping Analyses, University Institute of Legal Medicine, Lausanne, Switzerland

9.3.1 Introduction to Erythropoiesis

Erythropoiesis is part of the larger process of hematopoiesis, which involves the production of mature cells found in the blood and lymphoid organs. Hematopoiesis is continuously required because of normal turnover in the cell populations in the blood and lymphoid organs. In the normal adult human, the daily turnover of erythrocytes exceeds 10^{11} cells. In case of acute erythrocyte loss due to hemolysis or hemorrhage, the production of erythrocytes increases rapidly and markedly.

In hematopoiesis, rare hematopoietic stem cells in the bone marrow proliferate and differentiate so as to give rise to all the cellular components of the blood and the lymphoid system. During this process, an individual hematopoietic cell undergoes an apparent random process called commitment. When a cell undergoes commitment, its proliferation becomes limited and its potential to develop into multiple types of mature cells is restricted. Thus, these hematopoietic cells are termed committed, lineage-specific progenitor cells.

The major stages of differentiation in mammalian erythropoiesis are the following: The most immature stage of committed erythroid progenitors is the burst-forming unit-erythroid (BFU-E). The next major stage of erythroid progenitor cell development is the colony-forming unit-erythroid (CFU-E). A continuum of erythroid progenitor stages exists between the BFU-E and CFU-E, with decreasing proliferative potential as the progenitors approach the CFU-E stage. The descendant cells of the CFU-E are termed erythroid precursor cells. The erythroid precursors are proerythroblasts, basophilic erythroblasts, polychromatophilic erythroblasts, and orthochromatic erythroblasts. The orthochromatic erythroblasts do not divide but they enucleate, forming the nascent erythrocyte called the reticulocyte.

9.3.2 Production of Erythropoietin

EPO is a 30,400 D glycoprotein hormone produced mainly in the kidney, in the liver (<10%), and, in very small quantities, in the brain. The physiological stimulus for EPO production is tissue hypoxia, which, in the large majority of instances, is directly related to the number of circulating erythrocytes. Thus, EPO and erythropoiesis are part of a negative-feedback cycle that keeps tissue oxygen delivery within a narrow range by controlling the number of erythrocytes circulating in the blood. In a normal individual, any loss of erythrocytes, such as by bleeding or hemolysis, decreases delivery of oxygen to the tissues. When tissue hypoxia is sensed by cells capable of producing EPO in the kidney and liver, they produce and secrete EPO into the plasma. EPO is carried to the bone marrow, where it binds to specific cell-surface receptors on its target cells — the CFU-E, proerythroblasts, and basophilic erythroblasts. The binding of EPO by these cells increases their ability to survive and reach the reticulocyte stage and thereby contribute to the population of circulating erythrocytes. The increased numbers of circulating erythrocytes in turn deliver more oxygen to the tissues. This increased oxygen delivery is sensed by the EPO-producing cells, which then reduce EPO production so that the normal steady-state number of erythrocytes exists.

The response of the kidneys to hypoxia is exponential. That is, in individuals with a normal capacity to produce EPO, a linear decline in hematocrit is accompanied by an exponential increase in plasma EPO levels. This exponential increase is not based on the release of stored, pre-formed EPO. Rather, the hypoxia is sensed by an intracellular molecule that interacts with an enhancer element of the EPO gene and thereby induces transcription of the gene. The increase in EPO

production in the hypoxic kidney is achieved by recruitment of more cells to produce EPO. The EPO-producing cells of the kidney are a minor subset of cortical interstitial cells. Under normal conditions, only a few scattered cells produce EPO. When a threshold level of hypoxia is achieved, those cells capable of producing EPO do so at a maximal rate. The greater the areas of renal cortex in which the hypoxia threshold has been met, the greater the number of cells that produce EPO.

9.3.3 Mechanism of Erythropoietin Action

In the bone marrow, EPO binds to receptors displayed on the cell surface of CFU-E, proerythroblasts, and basophilic erythroblasts. The mature EPO receptor is an approximately 72,000 D, transmembrane glycoprotein that is a member of a much larger family of receptors of cytokines and hematopoietic growth factors. The effect of EPO binding to its receptor, in terms of cellular physiology, is the prevention of programmed cell death (apoptosis). In multiple systems of erythropoiesis, EPO has repeatedly been shown to be a survival factor for the erythroid cells in the later stages of differentiation from the CFU-E through basophilic erythroblasts. Although an effect of EPO on mitosis has been reported for BFU-E and an EPO-dependent cell lines, EPO is required only for the stages of CFU-E and later; apoptosis appears to result when EPO signaling cannot occur.

9.3.4 Detecting Recombinant EPO (rHuEPO) Abuse in Sports

As soon as rHuEPO became available in 1987, it was clear that this ergogenic hormone would be used illicitly in endurance sports. Therefore, the IOC Medical Commission decided specifically to ban it in 1990, even though all forms of blood doping had already been officially banned since 1984. Two approaches were developed for the detection of rHuEPO abuse. The first was based on the detection of indirect blood markers, and the second one was based on the direct detection of rHuEPO in urine. The rationale for using secondary blood markers was mainly based on the fact that they could be used to detect rHuEPO injections that had been given more than a week prior, and also because they could be used to detect all kinds of erythropoietic stimulators such as erythropoietin alpha, beta, omega, and Darbepoetin, as well as mimetic peptides. At the same time, scientists were working on methods for the direct detection of rHuEPO in blood or urine. This latter approach had the advantage of identifying the drug itself (or metabolites), but had the disadvantage of being expensive, not very sensitive, and delicate to perform.

9.3.4.1 Indirect Methods

In 1993, with the introduction of sophisticated hematological analyzers, some scientists proposed a model based on the analysis of the percentage of red blood cells having a hemoglobin concentration below 28 pg (MCH) and a volume above 128 fl (MCV). These red blood cells were called macrocytic hypochromatic erythrocytes. This test had the advantage of being fast and cheap (as long as the laboratory was equipped with this special analyzer) and was very selective. Unfortunately, the test was limited by a relatively poor sensitivity; 50% of the rHuEPO samples were not detected.

In 1996, another approach for the detection of rHuEPO-abuse, based on the determination of the soluble-transferrin-receptor (sTFR)/ferritin ratio. The results obtained during a trial involving healthy subjects demonstrated that regular rHuEPO injections significantly increased the sTFR concentration. Ferritin was used as a denominator mainly to prevent hydration level variations. Unfortunately, during this trial, the ferritin level declined, because the subjects did not receive an adequate iron supply. Knowing that iron supplementation was a common practice among athletes (especially intravenous iron injections), the sTFR/ferritin ratio was modified into a new ratio taking into account the possible exercise-induced hemoconcentration, the sTFR/total protein.

The lack of sensitivity of some of the secondary blood markers, as well as the lack of specificity of some others, fostered the idea of combining them together, and produce a mathematical model

Figure 9.3.1 Model showing the profile of mean hematocrit and reticulocyte count (SEM) during a continuous rHuEPO treatment with regular intravenous iron injections (see vertical bars). The study included three periods: baseline, treatment (ON), and post-treatment (OFF) periods.

to discriminate rHuEPO abusers from healthy sportsmen. Following a double-blind study with regular rHuEPO injections (continuous treatment), the Australian Institute of Sport together with the Australian Sports Drug Testing Laboratory designed an anti-doping test using multiple secondary blood markers such as the hematocrit level, the reticulocyte hematocrit, serum sTFR and EPO concentrations, and finally the percentage of macrocytic cells. Different mathematical models allowing the identification of athletes under rHuEPO treatment (ON-model) and those who took rHuEPO in the past days (OFF-model) were developed. In August 2000, the IOC Medical Commission approved the ON-model to be used during the Sydney 2000 Olympic Games. As the direct method capable of discriminating endogenous EPO from rHuEPO was published in spring 2000, the ON-model was only used as a screening test to determine which urine samples had to be collected to perform the urinary test.²³

At the same time the study was performed in Australia, the WADA accredited laboratory of Lausanne did a very similar controlled, randomized, double-blind trial, except that the importance of iron supplementation was recognized, and it was given intravenously to simulate the situation in cycling. Therefore, the behavior of secondary blood markers was different during the continuous treatment. Unlike the Australian study, the Swiss study found that some of the secondary blood markers (hematocrit, hemoglobin, and reticulocyte count) could be used as part of a screening test, but in no case could the multifactorial approach be used for anti-doping purposes (Figure 9.3.1).²⁴

9.3.4.2 Direct Methods

Endogenous EPO and rHuEPO are slightly different, and these differences stem from the glycosylation of rHuEPO, which takes place in Chinese hamster ovary (CHO) cells but not in human cells. Post-translational modifications are species and tissue dependent and also depend on the cell culture conditions. Therefore, it is possible to separate the endogenous from the exogenous EPO isoforms thanks to the differences of charges carried by the different sugar structures. This technique

Figure 9.3.2 Anti-doping urine analysis demonstrating the presence of rHuEPO in urine (see lane 4). 1. rHuEPO standard. 2. Positive urine (control). 3. Negative urine (control). 4. Sample declared positive. 5. Darbepoietine (Aranesp standard).

proved to be very reliable in urine and in blood, but only as long as the biological samples were collected within 24 h after the last rHuEPO injection. By 3 days after injection, less than 50% of the treated subjects could be declared positive. By 7 days after the last rHuEPO injection, none of the samples showed any traces of rHuEPO.

A few months before the Summer Olympic Games in Sydney, the French anti-doping laboratory in Paris published a paper in *Nature* describing a novel test based on the isoelectric focusing patterning and a double blotting protocol. Because the exogenous isoforms of rHuEPO are less acidic than endogenous EPO, it was possible to separate them using the isoelectric focusing method. This test was designed to separate alpha, omega, and beta rHuEPO (Figure 9.3.2).²⁵

9.3.4.3 Abnormal Blood Profiles

For approximately 2 years, laboratories have been encountering abnormal blood profiles in individuals with no traces of rHuEPO in their urine. This meant either that the athletes were doping with undetectable compounds or that they had returned to “ancient” doping techniques such as blood transfusion. Blood transfusion was common practice in the 1970s, used to enhance oxygen transport with the increase of red blood cell mass. This type of doping virtually disappeared with the arrival of rHuEPO at the end of the 1980s, because it is a much easier way to use the hormone (easy to store and use and cheaper). When direct testing of urine rHuEPO began in 2000, an unintended side effect was the return to blood transfusions.

Repeated and regular measurements of some blood parameters such as hematocrit, haemoglobin, and reticulocyte count showed that some athletes had abnormal blood parameters although rHuEPO could not be detected in urine. This indicated a return to blood transfusion practices. As erythrocytes differ from one person to another by membrane proteins, the Swiss Antidoping Laboratory (LAD) performed antidoping tests in blood for the first time in the summer of 2004. The analyses of some specific red blood cell membrane proteins in combination with flow cytometry showed that some abnormal blood profiles were due to homologous blood transfusion. Federations having introduced blood testing have a powerful tool to follow all athletes potentially abusing rHuEPO or blood transfusion.²⁶ Therefore, they need to focus their anti-doping tests mainly on those demonstrating abnormal blood profiles. This targeting aid also enables the federations to determine the prevalence

of doping methods, before any validated anti-doping test is on the market. In this way, for example, it was possible to determine that HBOC (hemoglobin based oxygen carrier) abuse was not a major problem, because none of the athletes tested had abnormal hematological indices.

9.3.5 Conclusion

It is nowadays possible to accurately detect blood doping and rHuEPO abuse complete detection. The necessity to take blood samples to screen and test for that type of doping habit has become obvious for sport authorities. But there is still a need for more research and coordination with other anti-doping panels in order to better target the use of blood manipulation. Hematological follow-up of the athlete is certainly one of the solutions for this targeting. In addition, new biochemical investigations should allow scientists to improve the tools for direct detection blood doping.

9.4 HUMAN GROWTH HORMONE

Martial Saugy, Ph.D.

Swiss Laboratory for Doping Analyses, University Institute of Legal Medicine, Lausanne, Switzerland

9.4.1 Introduction

Growth hormone (GH) is a naturally occurring peptide hormone secreted by the pituitary gland. Even if the hormone in the body is rather heterogeneous, the major component is made of 191 amino acids, stabilized by two disulfide bonds and reaching the molecular weight of 22 kD. Previously, the only source of GH was human cadavers, but the contamination of treated patients with a prion disease (Creutzfeldt–Jakob disease) made this form of treatment obsolete. Since the late 1980s, recombinant human GH (rGH) has been developed, and is available for the treatment of GH-deficient patients. This form of GH has an identical sequence to the naturally occurring 22-kDa peptide. Its abuse by athletes was suspected because of its anabolic properties. Some athletes claimed that the use of GH effectively increased the lean body mass and decreased fat content.

Today, the use of GH in sport is not only based on its anabolic properties, but also on its effect on the metabolism of carbohydrates and fat. Recombinant GH was detected in swimming and also during the Tour de France 1998.

International federations and the IOC included GH in the list of forbidden compounds in 1989, as it appeared quite obvious that recombinant GH would be more and more accessible, because of the new biotechnological methods making manufacture easier.

9.4.2 Growth Hormone and Exercise

The effect of acute exercise on growth hormone production in the body has been widely described in specialized literature.^{27–32} The GH concentration in blood increases with time for a given work intensity and can increase tenfold during prolonged moderate exercise. During a more intensive exercise with accumulation of lactate at 70% of $\text{VO}_2\text{-max}$ for a short-term period (10 to 20 min), the increase of GH will increase by fivefold to tenfold. Furthermore, it seems that GH response is more closely related to the peak intensity of exercise than to the total work output.^{33,34} Apart from the increase related to exercise itself, GH secretion can be increased by hypoglycemia, high temperature, and stress. The administration of exogenous GH cannot be differentiated from the physiological variations by observing GH levels alone.

9.4.3 Physiological Action of GH

GH is secreted by somatotrope cells in the anterior pituitary gland. Its secretion is pulsatile and is regulated by two hypothalamic peptides, growth hormone releasing hormone (GHRH), which stimulates GH secretion, and somatostatin, which inhibits GH secretion.³⁵ Women secrete slightly more GH than men and the highest levels are observed at puberty.³⁶ There is a decrease in GH secretion with age, by about 14% per decade. Moreover, its secretion is variable and higher GH levels have been observed during slow wave sleep, with exercise, stress, fever, and fasting.³⁷ Some specific drugs such as clonidine, L-dopa, and GHB (gamma-hydroxybutyrate) increase its secretion as well as androgens and estrogens. GH binds to specific receptors, which are omnipresent throughout the whole body.

9.4.4 Therapeutic Use of GH

GH is mainly used to treat GH deficiency and children with Turner syndrome. GH is also used in high doses to relieve the symptoms of excessive burns or thermal injuries. Major studies of GH-therapy in GH-deficient adults have demonstrated that rGH treatment for a period of 4 to 6 months has favorable effects on body composition, exercise aptitude, renal and cardiac functions, and generally improves quality of life. In long-term experiments, an increase of the bone mass with persistence of the above-mentioned effects has been observed. The positive effects on the body composition are essentially due to the anabolic, lipolytic, and anti-natriuretic properties. Doses in adults are generally individualized, but the mean dose is 1 to 2 IU/day applied subcutaneously every evening. No adverse side effects have been observed with therapeutic doses.

9.4.5 GH as a Doping Agent

Growth hormone has been considered an ergogenic drug since the late 1980s. Since that time, official and non-official sources report that its abuse in sport has steadily increased. The popularity of GH is based on widespread knowledge of its efficiency, difficult detection, and the fact that few side effects have been reported with conservative dosing. A survey reported GH abuse in 5% of male American high school students.³⁸ We do not know how popular GH is among female athletes, but some cases have been reported. One reason for a woman to use GH might be the absent risk of androgenic side effects in contrast to anabolic steroids.

The frequency of use and the dosage are difficult to evaluate. Underground sources stated doses of 10 to 25 IU per day, three to four times a week. Mean doses are probably about 4 IU/day and mostly combined with other doping agents (e.g., with anabolic steroids in power sports, or with EPO in endurance sports). The treatment is often applied in cycles of 4 to 6 weeks as for anabolic steroids in bodybuilding. In endurance sport, very little is known about the optimal use of GH. The doses involved are certainly adapted to the discipline, to the charge of training, and to the regimen of other ergogenic substances absorbed simultaneously.

The effectiveness of rGH for improving sport performance is still a subject of debate among abusers. The positive effects described in GH-deficient adults are not so evident for athletes. Many underground reports describe some positive effect on the muscle mass. The interpretation of such reports is difficult because of the combined use with other substances (e.g., anabolic steroids) leading to positive effects, and inefficient products on the market with no effect at all. Moreover, controlled studies did not confirm the spectacular effects described in underground reports from abusers, the efficiency of high dose GH being generally less impressive under controlled conditions.³⁹ The anabolic effect of GH is not the only one explored by athletes, as GH is also used in endurance sport in combination with oxygen transport enhancing methods.

It is difficult to draw any conclusions regarding the effects of excessive GH administration on skeletal muscle function. It must be also stressed that, today, GH may be used for purposes other than just increasing the muscle mass.

9.4.6 Detection of GH Doping

Until the Athens 2004 Olympic Games, GH was considered undetectable. Several factors complicate the detection of doping with GH:

GH is a peptide with a very short half-life in blood, and low concentration in urine.

GH is a peptide and to measure it the analyst must use nonclassic technologies.

The amino acid sequence of the recombinant molecule is identical to the major 22-kDa isoform, secreted by pituitary gland.

GH is not a glycoprotein like erythropoietin. Thus, the post-transcription modification of the molecule cannot be used to differentiate between the recombinant and the natural state.

Secretion of GH by the pituitary gland is pulsatile, leading to highly fluctuating levels in circulation, influenced by factors such as sleep, nutritional status, exercise, and emotion.

Secretion of GH shows high intra- and inter-individual variability.

9.4.6.1 The Urine Strategy

Anti-doping urine samples are mostly collected out of competition or after effort. Because of their availability in high volume, convenient collection, and longer detection time window in contrast to blood, attempts for peptide detection were made in urine. This was successful for EPO, but much less so for GH. In urine, the average concentration of GH is between 100 and 1000 times lower than in blood. An extremely sensitive immune test was used to quantify the total amount of the hormone in urine, but lack of sensitivity and specificity of the result made the urinary test less promising than blood testing.⁴⁰

More stable serum parameters, such as those implied in the biological cascade produced by GH secretion or application, may provide the best route for detection of GH. Growth factor (IGF-1), or some of its transport proteins (IGFBP-3), has been proposed as a possible candidate for indirect detection of GH doping.⁴¹ But their inter-individual variability is also quite high and makes a quantitative cutoff level hard to define precisely.

9.4.6.2 The Indirect and Direct Approaches in Blood

Two main strategies are currently being followed to detect GH doping in blood.⁴²

The Indirect Approach

Increasing knowledge about the naturally occurring variability of several GH-dependent parameters, such as the growth factor IGF-1, the different IGF binding proteins (IGFBPs), and several markers of bone turnover,⁴³ may provide data for establishing individualized normal ranges for concentration and normal constellation of these parameters. This approach did not, however, bring a final solution for detection of GH doping. The indirect approach still may be useful for screening and targeting purposes that allow for the identification of probable GH abusers.⁴⁴

The Direct Approach

The Strasburger-Bidlingmaier group in Munich developed a so-called direct method for the detection of GH doping.⁴⁵ Two specific immunoassays allow the quantification of the several GH isoforms. Recombinant GH consists exclusively of the 22-kDa form, whereas physiological GH is present in several forms, as shown Table 9.4.1.

When the recombinant form is injected in the body, a transient increase of the 22-kDa form will be observed, modifying its ratio in comparison to the other circulating forms. Moreover, long-term treatment will inhibit the endogenous secretion of GH by a classical feedback regulation,

Table 9.4.1 Relative Abundance of GH Molecular Forms in Circulation (the percentages are approximate)

Isoforms	%
22-kDa monomer	48
20-kDa monomer	9
Modified GH (dimers and oligomers)	30
Acidic GH (desaminated and acylated forms)	7
Fragmented GH (17, 12, 5, 30kDa)	Variable

Source: Adapted from Bidlingmaier et al.⁴⁵

Figure 9.4.1 Molecular basis of direct detection of GH abuse by differential immunoassay: A ratio is calculated between the signals given by the Assay 1 to the signal given by the Assay 2. Two of these double tests must be performed in case of positive result in order to confirm the diagnostic. (Adapted from Bidlingmaier et al.⁴⁵)

resulting in an even bigger relative increase of the 22-kDa form. This test was used during the Olympic Games in Athens. To fulfill the requirements of the WADA Code, and the standards for laboratories, two double tests have been applied successively to serum samples: the first test is for quantifying specifically the 22-kDa form, and the second is a comprehensive assay measuring all forms present in the serum. The ratio was then calculated and a cutoff-level has been defined to differentiate the normal subjects (negative samples) from those having a significantly higher proportion of 22-kDa GH (positive samples) (Figure 9.4.1). A second double test was used for confirmation purposes.

Depending on the dosage, the detection window for these tests is between 24 to 36 hours after the last injection. This test may act as a deterrent if applied in and out of competition. It has been shown also that this direct test is not influenced by environmental parameters such as exercise or stress. The example illustrates that the fight against doping must evolve in new analytical techniques and new strategies based on different biological matrices.

9.5 CANNABINOIDs

Christian Giroud, Ph.D.

University Institute of Legal Medicine, Lausanne, Switzerland

The relative high incidence of cannabinoids detected in urine (see Tables 9.2 and 9.3 above) reflects the high prevalence of cannabis use among young adults. Various studies carried out in Europe and elsewhere have shown an impressive increase in the frequency and quantity of consumption, essentially in the younger population, with an ever earlier onset of use. According to the

report of the European Monitoring Center for Drugs and Drug Addiction (2005), 1.2 to 16% of young people aged 15 to 24, from 18 European countries, indicated cannabis consumption during the last month while 16% of young U.S. adults aged 18 to 25 reported past month use of cannabis (Substance Abuse and Mental Health Service Administration report, 2004).

Because cannabis smoking impairs cognition, psychomotor, and exercise performance, it is considered an ergolytic drug. Renaud and Cormier⁴⁶ have shown that marijuana smoking reduces maximal exercise performance: when 12 healthy young adults cycled to exhaustion 10 min after smoking, exercise duration was shortened from 16 to 15 min. Driving and piloting skills are also negatively affected, pointing out the danger of cannabis exposure when high levels of alertness and quick reflexes are required such as in automobile sports.⁴⁷ It can be inferred from the psychological effects of marijuana that cannabis may be efficient in allowing the athlete to relax and to escape from social pressures. The main features of recreational use of cannabis are a feeling of euphoria, decreased anxiety, and increased sociability, which may alleviate the stress generated by competition. However, cannabis can also produce dysphoric reactions, including severe anxiety⁴⁸ and panic disorders, paranoia, and psychosis.^{49,50}

These unwanted reactions are more common in naïve, anxious subjects and psychologically vulnerable individuals and appear more frequently after ingestion than after smoking. Cannabis diminishes alertness and has relaxing and sedative properties; it may therefore be used to improve sleeping time and quality. Lorente and co-workers⁵¹ reported that relaxation, feelings of well-being, and improved sleep were the main effects that motivate the use of cannabis in French sport science universities. Athletes engaged in “X-treme” sports are more prone to cannabis use. A relationship between drug use and “sensation seeking” behavior has been often reported. Competition level is also considered as a risk factor for cannabis use, with a view to coping with stress and anxiety.⁵²

According to the IOC, urine samples are considered positive for cannabis exposure if the sum of the concentrations of free and conjugated carboxy-THC is greater than 15 ng/ml (when determined by GC/MS). This threshold value distinguishes active users from passive smokers.⁵³ It also reduces the risk of a positive result due to commercial food products containing traces of cannabinoids.^{54,55} Since the mid-1990s, the use of food products containing seeds or hemp seed oil has increased considerably in several Western countries. However, several countries have enacted THC regulatory limits for foodstuffs and beverages lowering THC intake from hemp food and reducing the risk of a positive urine test. Regulations in Canada, the main supplier of hemp seeds to the U.S., limit THC levels in hemp seed products to 10 parts per million (ppm) (Industrial Hemp Regulations, Schedule No. 1089, Canada).

Several other problems should be mentioned in relation to carboxy-THC analysis in urine. First, the relevance of the 15 ng/ml cutoff value could be improved by normalizing the urine concentration to the creatinine level. Through this approach, quantitative results are corrected for urine dilution and possible adulteration. Prediction of repetitive or new marijuana use by analyzing the urinary cannabinoid-to-creatinine ratio in two consecutive urine samples collected at least 24 h apart are also possible.⁵⁶ Quantification of carboxy-THC in urine does not allow deducing the time of last marijuana use and there is no relationship between urine concentrations and psychomotor effects. Huestis and co-workers⁵⁷ have shown that occasional users of marijuana had positive urine specimens for 3 to 4 days after receiving a defined dose of marijuana. In heavy smokers, urine specimens remained positive for 4 to 28 days (median value: 16.6 days) after last drug use.⁵⁸ Ellis et al.⁵⁹ reported an average time until the last positive result of 31.5 days (4 to 77 days) in urine for THC metabolites screened by immunoassay with a cutoff value of 20 ng/ml. According to Manno et al.,⁶⁰ determination of the time of last cannabis use is possible by measuring total THC in urine. Significant levels of THC could be measured by using a hydrolysis step in the extraction protocol. A concentration greater than 2 ng/ml would suggest marijuana use within a 5-h time window, a time during which psychological and performance effects are known to occur.

9.6 ETHANOL USE IN SPORT AND INTERACTION WITH OTHER DOPING AGENTS

Alcohol (ethanol) is prohibited in-competition only, in a limited number of sports (e.g., automobile, archery, modern pentathlon for disciplines involving shooting). Sport federations have set up cutoff limits in blood, which are regularly updated. They range between 0.1 and 0.3 g/L for 2006. The basis of the ban is the antitremor effect of low-dose ethanol that may enhance shooting performance.⁶¹ Even at low concentrations, alcohol disrupts many motor performances and can interfere with complex activities such as skiing or driving. Alcohol is therefore prohibited for obvious safety reasons. Because, there have been cases of athletes using alcohol to boost their aggressiveness and confidence, alcohol is prohibited in some fighting sports (karate). Alcohol is often ingested because of its exhilarating and anxiolytic effects: drinking after the game is considered as a good way to unwind. Ethanol is also known to interact with a large array of pharmacological active substances, including steroids, analgesics, and stimulants.^{62,63} Combination of AAS with ethanol may contribute to the increase in aggressive behavior.

9.7 MORBIDITY OF DOPING

Marc D. Bollmann, M.D. and Patrice Mangin, Ph.D.

University Institute of Legal Medicine, Lausanne, Switzerland

The clinical and pathological findings are often difficult to associate with a specific drug for numerous reasons. On one hand the tissue reaction to different forms of injury is rather uniform (e.g., chemical, physical, hypoxic, immunological), ending in inflammation and fibrosis. On the other hand the end-stage mechanism of abused substances is often similar (e.g., stimulant catecholamine toxicity). The following examples illustrate the adverse effects of some commonly abused substances.^{64,65}

9.7.1 Anabolic-Androgenic Steroids (AAS)

AAS are widely used and effective in enhancing athletic performance, even in recreational sports. In a survey of 1881 schoolchildren aged from 13 to 17 years in Georgia, 6% of boys and 2% of girls reported taking androgens without a physician's prescription. The trade-off, however, is the occurrence of adverse side effects and even sudden death, reported mostly among weightlifters and bodybuilders.⁶⁶⁻⁶⁸ In general, the orally administered AAS have more adverse effects than parenterally administered AAS. In addition, the type of AAS is not only important for the beneficial effects, but also for the adverse effects. AAS containing a 17-alkyl group have more potential to exert adverse effects, in particular in relation to the liver. One of the problems with athletes, in particular strength athletes and bodybuilders, is the use of oral and parenteral AAS at the same time ("stacking"), and in dosages that may be several times (up to 40) the recommended therapeutic dose. The frequency and severity of side effects are quite variable. It depends on several factors such as type of drug, dosage, duration of use, and the individual sensitivity and response. Since AAS have effects on almost all organ systems, myriad side effects can be found.

9.7.1.1 Cardiovascular

Chronic administration of anabolic steroids causes a reversible reduction in serum high-density lipoprotein (HDL) levels. Since HDL binds cholesterol and renders it inert, reduced HDL levels

^a LVT = left ventricular thickness.

are associated with arteriosclerosis and enhance the risk of coronary heart disease.^{69,70} AAS can enhance the vascular responsiveness to catecholamines and may favor effort-triggered arrhythmia.⁷¹ The effects on protein synthesis may involve the myocardium and can lead to hypertrophy and shortage in oxygen delivery. The cardiac afterload may increase by water retention, which represents another source of cardiac hypertrophy. The combination of these effects can lead to a higher oxygen demand with less oxygen delivery and consequently myocardial cell death and scars, with the inherent risk of lethal reentry tachyarrhythmia. Table 9.7.1 shows a summary of case reports concerning anabolic steroid abuse associated with sudden death. Left ventricular hypertrophy is encountered in almost all of these cases.

9.7.1.2 Hepatic

AAS may exert a profound adverse effect on the liver. This is particularly true for orally administered AAS. Less adverse effects are reported for parenterally administered AAS. In this respect testosterone cypionate, testosterone enanthate, and other injectable anabolic steroids seem to have little adverse effects on the liver. However, lesions of the liver have been reported after parenteral nortestosterone administration, and also occasionally after injection of testosterone esters. The influence of AAS on liver function has been studied extensively. The majority of the studies involve hospitalized patients who are treated for prolonged periods for various diseases, such as anemia, renal insufficiency, impotence, and dysfunction of the pituitary gland. In clinical trials, treatment with anabolic steroids resulted in a decreased hepatic excretory function. Even liver neoplasia has been reported,⁶⁹ but the number of cases is few and causality remains uncertain.

9.7.1.3 Endocrine/Reproductive

Exogenous AAS reduce serum testosterone levels, which may decrease male fertility. In one study, sperm count fell by 73%, and in three individuals aspermia (complete absence of sperm) was found, when high doses of anabolic steroids were taken chronically. In-depth interviews with 110 AAS users revealed that 56% of the males reported testicular atrophy; 62% of the females had menstrual irregularities. Gynecomastia occurs because testosterone is converted to estradiol via the action of the aromatase enzyme complex, so that high doses of testosterone result in high serum estradiol concentrations. Other side effects have been reported including baldness, virilization and premature epiphyseal fusion and stunting of growth. The effects on the coagulation system are controversial.

9.7.1.4 Psychological

Administration of AAS may affect behavior. Increased testosterone levels in the blood are associated with masculine behavior, aggressiveness, and increased sexual desire. Increased aggressiveness may be beneficial for athletic training, but may also lead to overt violence outside the gym or the track. There are reports of violent, criminal behavior in individuals taking AAS. Other reported side effects of AAS are euphoria, confusion, sleeping disorders, pathological anxiety, paranoia, hypomania, or major depression.⁷⁸

9.7.1.5 Tendon Injuries

Tendon rupture has been linked with AAS use on the basis of a small number of published case reports, and it has been suggested that these drugs predispose the tendon rupture by altering collagen structure. It is also possible that the rapid increase of skeletal muscle produced by AAS is not matched by the slower adapting tendon structures, making tendons the weakest link in the chain.

9.7.2 Stimulants

Stimulants are the second big group of currently abused drugs. Amphetamine was widely ignored until the 1960 Olympics, when the Danish cyclist Knut Jensen died of a speed-induced heart attack during a race. During the 1967 Tour de France, the British cyclist Tom Simpson collapsed and died. A vial of methamphetamine was found in his pocket at the time of his death. The impact of his death was extensive, in part because it was the first “doping death” to be televised.

One should suspect stimulant abuse in cases of hyperthermia, dehydration and all forms of overtaxing the body. Elite athletes are also at risk for out-of-competition stimulant (especially cocaine) abuse, partly because of the constant pressure they live under and the confrontation with celebrity, news media, and fans, for which they are often unprepared. Cocaine should be tested for in every case of sport-related sudden death.

9.7.2.1 Amphetamine

Some side effects of amphetamine are particularly important in athletes and do not only include headaches, sleeplessness, and anxiety. Indeed, amphetamine use may carry significant health risks for the sportsman, as evidenced by several amphetamine-linked deaths in sport. Two of the major risks are the amphetamine-induced heatstroke and cardiac arrest. Hyperthermia may be attributed to an increase in physical activity and peripheral vasoconstriction, making it difficult for the body to cool down. The ability of amphetamine to obscure painful injuries has enabled athletes in some sports to compete by exacerbating their injuries. The side effects of amphetamine on behavior are another important factor in sport. Amphetamine administered to promote aggression and euphoria, while weakening the sensation of fatigue, has led to misjudgments and major fouls on the pitch.

9.7.2.2 Cocaine

Classical physical effects of cocaine use include peripheral vasoconstriction, mydriasis, thermogenesis, and increased heart rate and blood pressure. These symptoms lead to an overall higher workload for the heart, and increase its oxygen demand. On the other hand, vasoconstriction of coronary arteries may make it impossible to meet the oxygen demand. This may lead to acute arrhythmia, favored additionally by an altered excitability of the cardiomyocytes (e.g., QT-prolongation), and/or structural damage (e.g., fibrosis and microvascular disease) to the heart.^{79–81} A

number of dramatic fatalities associated with coronary occlusion have occurred in cocaine abusing athletes, usually those who have been exercising following drug administration. Cocaine abuse is strongly associated with cerebrovascular accidents arising from either the rupture or spasm of cerebral blood vessels.⁸²

Cocaine is highly addictive, and with increasing doses, it may lead to a state of irritability, restlessness, anxiety, and paranoia. Cocaine is often consumed in combination with other drugs, enhancing the toxic effects, especially on the heart. Some fatalities have also occurred when cocaine has been combined with alcohol or anabolic steroids.

9.7.2.3 Ephedrine

Common side effects of ephedrine are qualitatively similar to those produced by amphetamines, but are generally milder: headache, dizziness, irritability, anxiety, tremor and psychosis. Higher doses (overdose) can cause restlessness and anxiety, dizziness, insomnia, tremor, rapid pulse, sweating, respiratory difficulties, confusion, hallucinations, delirium and convulsions. The most dangerous symptoms of overdose are arterial hypertension peaks and cardiac arrhythmia. Finally, a number of instances of psychosis, clinically similar to amphetamine psychosis, have resulted from chronic high-dose abuse.

There are serious doubts about the safety of food supplements containing ephedra-alkaloids. Because supplements are not considered therapeutic, they are not under the same strict surveillance as prescribed and over-the-counter medications. Because of recent highly publicized tragedies, various athletic associations have focused on further evaluations of the use of these substances and are trying to warn athletes about the potential health risks associated with their use.

9.7.3 Erythropoietin

Erythropoietin is still a widely used and efficient doping method. An interesting illustration of the problem may be the industrial production of erythropoietin covering about 10 times the medical needs.⁸³ In theory the main risk of erythropoietin abuse would be thrombosis because of the increased viscosity of the blood. Only one case of a survived cerebral sinus thrombosis in a professional cyclist has been reported after admitted erythropoietin abuse.⁸⁴

9.7.4 Human Growth Hormone (GH)

The long-term risks due to utilization of GH are not well known. Acromegaly, describing a pathological increased endogenous production from a pituitary tumor, would be expected after excessive use of GH. The major symptoms are the swelling of the hands and feet, coarsened facial appearance, dentition problems, arthralgia, fluid retention, and excessive sweating. Acromegalic patients have increased risk for diabetes mellitus and hypertension defined in total by premature mortality from cardiovascular diseases. There are also risks of developing osteoporosis, menstrual irregularities, and impotence. Arthralgia and myalgia have, however, been reported in more than 50% of treated subjects.⁸⁵ Some of these side effects are certainly reversible after withdrawal of the drug. Furthermore, GH abuse can disturb lipid pattern with decreased HDL-cholesterol.

Epidemiological data regarding that type of treatment in healthy sportsmen are missing as well as scientific reports about the mentioned side effects. Reports of oversize shoes in tennis players and swimmers are anecdotic.

Since GH is administered by injection, there is a great risk of cross infections such as HIV and hepatitis if syringes are contaminated. GH was once extracted from human bodies, which implied a risk of Creutzfeldt-Jakob disease⁸⁶ characterized by a progressive dementia.

9.8 MORTALITY OF DOPING — SUDDEN DEATH IN ATHLETES

Marc D. Bollmann, M.D.

University Institute of Legal Medicine, Lausanne, Switzerland

Athletes are thought to represent the healthiest segment of our society and they are highly visible. For these reasons, the sudden death of an athlete has a large impact and receives much attention. The incidence of sudden death in athletes is estimated 2.5 times higher than in non-athletes.⁸⁷ It has also been shown that almost every single case of sudden death in athletes was due to an underlying hereditary or acquired heart disease, in which effort might trigger arrhythmia.^{87–89} In only about 1% of the examined cases could drug abuse be confirmed. The main pathologies accounting for more than 80% of sudden deaths in young athletes are the following:

Hypertrophic cardiomyopathy (HCM)⁹⁰ is a relatively common genetic cardiac disease (1 in 500), with heterogeneous clinical, morphologic, and genetic expression. To date 12 disease-causing loci have been identified, mostly encoding for thick filament components in cardiomyocytes. The heart action may be normal or even more vigorous; this may also explain the high incidence of the disease in athletes. The morphological characteristics of the disease are an asymmetrical, hypertrophied, and non-dilated left ventricle, disorganized myocardial architecture, and replacement scarring. Some variations are, however, not easily diagnosed. When in doubt, the medical history of a victim and his or her family can be helpful to differentiate an athlete's heart from an HCM. If the left ventricular wall thickness exceeds 13 mm, an underlying pathology and/or substance abuse must be suspected, even in a young population of well-trained athletes.⁹¹ Genetic analysis can be performed for known mutations.^{92,93} Hypertrophy alone may, however, be drug induced (e.g., by anabolic steroids).

Arrhythmogenic right ventricular cardiomyopathy (ARVC) also accounts for numerous sudden deaths in athletes.⁹⁴ The right heart muscle is replaced with fatty and fibrous tissue, altering conductivity and leading to fatal arrhythmia. Sudden death is often the first symptom. So far five genes have been identified as containing mutations for ARVC. The first one is the cardiac ryanodine receptor, which regulates intracellular Ca^{2+} . A dysfunction in the same receptor is held responsible for catecholaminergic polymorphic ventricular tachycardia, which is characterized by exercise-induced fatal arrhythmias without any morphologic heart disease.⁹⁵ For reasons that remain unexplained, this syndrome is reported with much greater frequency in Europe than in the U.S.

Long-QT syndrome and Brugada syndrome are two common hereditary channelopathies. Fatal arrhythmia can occur, and drugs of many kinds can facilitate or induce it.

Congenital malformations such as mitral valve prolapse or anomalies of coronary arteries (especially those in which the anomalous coronary artery makes an acute bend and courses between the pulmonary artery and aorta).

A problem with the mentioned studies, however, is the often missing or incomplete toxicological analysis. So even if a possible or probable cause of death is found at the autopsy, there remains doubt about a substance-triggered or facilitated sudden death (e.g., coronary thrombosis with evidence of EPO abuse, stimulants, and channelopathy). Another factor to bear in mind is the growing analytical possibilities, which may place many old cases of natural death in a new context. For all the above reasons toxicological investigation should be carried out in every case of sudden death in athletes. In the news-media-driven environment of sports, the suspicion of doping will sooner or later come up anyway.

Substance abuse as sole cause of death in athletes is, however, very rare (in spite of the mainly historic cases of lethal cocaine, strychnine, or amphetamine levels). Doping and substance abuse should rather be considered supplementary risk factors for sudden death because they permit one to overtax the organism and may contribute to structural disease. Another mechanism is the modification of cellular excitability and/or induction of an acquired long-QT interval (e.g., cocaine

induced).⁸⁰ Combined with other factors like acquired and/or hereditary heart disease, adverse weather conditions (heat with dehydration and electrolyte disorder), or simply effort, a high-risk situation for lethal arrhythmia can arise. If substance abuse is involved in the mechanism of death, an investigation of the circumstances should be carried out. As efficient doping practice is only possible with a close medical follow-up, one should also look for possible medical malpractice.

The sudden death of an athlete is difficult to solve and requires a multidisciplinary approach and careful investigation. Athletes are considered the healthiest segment of society, and so the sudden death of an athlete has considerable impact and the hypothesis of doping is easily advanced. However, most cases of sudden death in athletes are related to an underlying hereditary cardiovascular disease. The possibilities to diagnose hereditary heart disease are now growing steadily. Genetic testing may also be helpful to provide advice and lower the risk for the relatives of the victim. Preventive measures have been taken to prevent morbidity and mortality in athletes, for example, using medical follow-up and screening, carried out by team-independent physicians. Athletes at high risk of sudden death may be excluded from competition. Some international and national sports federations have already taken steps in this direction.

Drug abuse is widespread in sports and the already large arsenal of analytical methods should be used and improved. Reports about dangerous side effects alone do not act as a deterrent. In a survey conducted by *Sports Illustrated*, athletes were asked if they would take a performance-enhancing drug if they would win and not be caught. Of 198, 195 answered “yes.” A second question asked them if they would take a substance making them win every competition for 5 years, but with the drawback of dying of its side effects. Still more than 50% answered “yes.”⁹⁶

9.9 THE FUTURE OF DOPING: NEW DRUGS AND GENETIC DOPING

Christian Giroud, Ph.D.¹ and Marc D. Bollmann, M.D.²

¹ Swiss Laboratory for Doping Analyses, University Institute of Legal Medicine, Lausanne, Switzerland

² University Institute of Legal Medicine, Lausanne, Switzerland

The pharmaceutical industry is continuously looking for new blockbusters and “smart” drugs. New areas of research include the production of drugs able to alter the aging process, and maintain muscle integrity. Both would be possible candidates for future doping agents. Peroxisome proliferator-activated receptor ligands (PPAR) are new drugs that are now being investigated for using against cardiovascular disease and syndrome-X. They increase fat burning and may enhance sports performance by changing fast glucose-burning muscle fibers into fat-burning muscle.⁹⁷ Wang et al.⁹⁸ have shown that activation of PPAR- δ in mice leads to muscle fiber transformation, and enhances physical performance and exercise endurance. According to Azzazy et al.,⁹⁹ the main candidates of gene doping are erythropoietin, human growth hormone, insulin-like growth factor-1, PPAR- δ , myostatin inhibitor genes, and hypoxia-inducible factors. Genes encoding for analgesic opioids such as endorphins and enkephalins constitute another valuable target. Altering behavior, alertness, anxiety, and psychological resistance to stress may be possible with gene transfer in the limbic system of the brain.¹⁰⁰ The roots of gene doping lie in gene therapy, for which only very few therapeutic successes have been achieved to date (December 2005). Nine French infants suffering from severe combined immune deficiency (X-SCID) were cured by gene therapy of their own bone marrow cells. However, due to proviral insertional oncogenesis, two individuals developed T-cell leukemia more than 2 years after the gene transfer.¹⁰¹ The paucity of successful results and the high incidence of serious side effects cast doubt on the use of genetic engineering methods in sports in the near future. It should also be noted that genetic doping is detectable by existing techniques as recently demonstrated by Lasne and co-workers.¹⁰²

10.1 DRUGS IN THE WORKPLACE

Yale H. Caplan, Ph.D., DABFT,¹ and Marilyn A. Huestis, Ph.D.^{2*}

¹ National Scientific Services, Baltimore, Maryland

² Chemistry and Drug Metabolism Section, Intramural Research Program, National Institute on Drug Abuse, National Institutes of Health, Baltimore, Maryland

Substance abuse has been a mainstay of society for the past few millennia. Epidemics come and go in somewhat predictable cycles and the problem has never been resolved. Over the past century, as this cyclic equilibrium has shifted, the magnitude of the problem has generally intensified. The number of euphoric substances has grown and their enhanced distribution has increased abuse. Technology has increased the potency of euphoric compounds, i.e., the synthesis of natural opium to heroin and the *de novo* synthesis of non-natural substances such as PCP, LSD, MDMA, and others. Cocaine has been concentrated and modified from the coca plant to produce freebase and crack cocaine. Improvement in horticulture techniques has increased the content of marijuana to 10 to 15% tetrahydrocannabinol (THC).

Workplace drug and alcohol testing is the latest component to be added to the discipline of forensic toxicology, which now comprises the triad fields of post-mortem, human performance, and workplace drug testing toxicology. Since drug testing is conducted as a deterrent to drug abuse, and society seeks to protect the rights of individuals in the workplace, every effort is necessary to prevent harm to persons through false accusation. Drug testing is a multifaceted process. The accuracy and validity of analysis and the use and application of the reported results are concerns. Multiple factors include the methodologies (initial and confirmatory), cutoff concentrations, administrative or legally mandated rules, and the influence of prescribed drugs or environmental exposure.

Acquiring a full understanding of workplace drug testing is necessary for practitioners (toxicologists, physicians, and others). The tenets of forensic science and regulatory requirements influence workplace drug testing. The right questions must be asked and proper caveats applied. Traditionally in medical practice, the test result is only one part of the diagnostic paradigm that also includes history and physical examination. In workplace testing, the test result is the primary and paramount element. There is no diagnostic paradigm and the result must stand alone evaluated only after the test event by medical personnel identified as a medical review officer (MRO).

Workplace testing is employed to ensure safety and productivity in the workplace. It is complex with myriad elements vital to its success. This chapter and those to follow will overview workplace drug testing including its background and current status, its regulatory basis, its application in the U.S. and abroad, analytical approaches, the use of urine and other biological matrices, quality

* Dr. Huestis contributed to this book in her personal capacity. The views expressed are her own and do not necessarily represent the views of the National Institutes of Health or the U.S. government.

control and validity testing, the role of the MRO, and associated legal issues. Although alcohol testing and on-site (point of collection) testing are practiced in the workplace, they are not included in this chapter; rather, they are discussed in other sections of this book.

10.1.1 History

Workplace drug testing has grown at a steady rate over the last 20 years. It is recognized that employee/applicant drug testing has become a standard business practice in the U.S. It is likely that almost half of the American workforce will be tested for illegal drugs this year. A more detailed history was provided in the earlier edition of this book.¹

The workplace drug-testing phenomenon did not occur overnight, but rather evolved slowly during the 1980s. At the outset, workplace drug testing began in the U.S. military with most of the testing done in military laboratories by military personnel. Testing was highly regimented; however, even within the military programs (Army, Navy, and Air Force), procedures, equipment, and standards varied considerably. As the use of the new immunoassay-based drug-testing technology spread to the private sector in 1982–1983, there were no regulations, no certified laboratories, no standardized procedures, and many of the devices marketed for testing were not cleared by the U.S. Food and Drug Administration. Medical and scientific questions concerning the accuracy and reliability of drug testing were raised continuously by those who opposed testing and often formed the basis of lengthy litigation. As interest in workplace drug testing increased in the public and private sectors, the need for regulations to establish the appropriate science, technology, and practice became obvious.

The beginnings of regulated testing were initiated in 1983 when the National Transportation Safety Board (NTSB) sent a series of specific recommendations to the Secretary of Transportation demanding action in regard to alcohol- and drug-related accidents, particularly in the railroad industry. The report indicated that seven train accidents occurring between June 1982 and May 1983 involved alcohol or other drugs. In response to the NTSB recommendations, the Federal Railroad Administration (FRA) with the assistance of the National Institute on Drug Abuse (NIDA) began to develop the first Department of Transportation (DOT) drug regulations in 1983. However, it was not until early 1986 that legal obstacles were cleared and the rule went into effect and was fully implemented. During the 1983–1986 timeframe, many companies in the oil, chemical, transportation, and nuclear industries voluntarily implemented drug-testing programs. Without standards and recognized procedures, almost every action incurred controversy. Lawsuits and arbitration caseloads mounted rapidly. Reports of laboratory errors in the massive military program raised concerns that the application of this state-of-the-art technology might be premature. Allegations of employees stripped naked and forced to provide specimens in view of other employees were often repeated and added justification for regulations.

In 1986, the federal government became involved in employee drug testing in a significant way. In March 1986, President Reagan's Commission on Organized Crime issued its final report. Among the recommendations were the following:

The President should direct the heads of all Federal agencies to formulate immediately clear policy statements, with implementing guidelines, including suitable drug testing programs, expressing the utter unacceptability of drug abuse by Federal employees. State and local governments and leaders in the private sector should support unequivocally a similar policy that any and all use of drugs is unacceptable. Government contracts should not be awarded to companies that fail to implement drug programs, including suitable drug testing. Government and private sector employers who do not already require drug testing of job applicants and current employees should consider the appropriateness of such a testing program.

NIDA convened a conference in March 1986. The conference was designed to discuss and achieve consensus on drug-testing issues. Prior to the release of the President's Commission on

Organized Crime report, the NIDA position advocating testing for critical and sensitive positions was viewed as radical. However, once the recommendation for widespread testing of everyone employed in both the public and private sectors was proposed by the President's Commission, the NIDA position became one of reasonable accommodation. The conference thus focused on prescribing the conditions under which testing could be conducted. After lengthy discussions, consensus was reached on the following points:

1. All individuals tested must be informed.
2. All positive results on an initial screen must be confirmed through the use of an alternate methodology.
3. The confidentiality of test results must be assured.
4. Random screening for drug abuse under a well-defined program is appropriate and legally defensible in certain circumstances.

The consensus reached at this meeting in 1986 on technical, medical, legal, and ethical issues truly served to provide the foundation for the development of the federal regulations that were to evolve over the next decade and continue to evolve. The responsibility for developing technical and scientific guidelines for these drug-testing programs was assigned to the Secretary of Health and Human Services (HHS) and was delegated to NIDA. An informal advisory group produced the initial set of guidelines in a matter of months. On February 19, 1987, HHS Secretary Dr. Otis Bowen issued the required set of technical and scientific guidelines for federal drug-testing programs. Several months later Congress passed a new law (Public Law 100-71 section 503) that set the stage for the widespread regulation of employee drug testing. Enacted on July 7, 1987, the law permitted the President's *Drug Free Federal Workplace* program to go forward only if a number of administrative prerequisites were met. Among the list of required administrative actions was that the Secretary of Health and Human Services publish the HHS technical and scientific guidelines in the *Federal Register* for notice and comment, and to expand the "Guidelines" to include standards for laboratory certification. The NIDA advisory group had been working on the concept of laboratory accreditation since early in 1986 anticipating the eventuality of laboratory certification. This allowed NIDA to revise the "guidelines" quickly and include a proposed scheme of laboratory certification, which was published in the *Federal Register* on August 13, 1987, less than 6 weeks after the passage of the law.

The HHS Guidelines included procedures for collecting urine samples for drug testing, procedures for transmitting the samples to testing laboratories, testing procedures, procedures for evaluating test results, quality control measures applicable to the laboratories, record keeping and reporting requirements, and standards and procedures for HHS certification of drug-testing laboratories. The basic intent of the guidelines was and remains to safeguard the accuracy and integrity of test results and the privacy of individuals who are tested. Following comment and revision, the scientific and technical aspects of the guidelines remained intact as drafted and were published in the *Federal Register* as the "Mandatory Guidelines for Federal Workplace Drug Testing Programs" on April 11, 1988. In July 1988, utilizing the certification standards developed as part of the "Mandatory Guidelines," a National Laboratory Certification Program was implemented by HHS/NIDA and was administered under contract by the Research Triangle Institute. More than 100 laboratories have been certified in this program since 1988 with approximately 50 remaining certified in 2006.

The U.S. DOT published an interim final rule on November 21, 1988 establishing drug-testing procedures applicable to drug testing for transportation employees under six DOT regulations. These six regulations were published on that same date by the Federal Aviation Administration (FAA), Federal Highway Administration (FHWA), Federal Railroad Administration, U.S. Coast Guard, Urban Mass Transportation Administration, and Research and Special Programs Administration. The interim final rule (49 CFR part 40) followed closely the HHS regulation entitled "Mandatory Guidelines for Federal Workplace Drug Testing Programs." DOT issued its final rule

on December 1, 1989 with an implementation date of January 2, 1990. These regulations brought the rest of the transportation modes in line with the railroad industry and, in most aspects, standardized the procedures across the industry. The Congress later passed the Omnibus Transportation Employee Drug Testing Act of 1991. This Act was an extremely important piece of legislation that broadly expanded drug testing in the transportation industry. The impetus for the legislation was a very visible subway accident in New York City where the engineer was found to be under the influence of alcohol. The Act required DOT to prescribe regulations within 1 year to expand the existing DOT drug regulations in aviation, rail, highway, and mass transit industries to cover intrastate as well as interstate transportation and to expand the drug-testing program to include alcohol. Final DOT rules were published in the *Federal Register* in February 1994, which continued to incorporate the HHS “Guidelines” and required implementation by January 1, 1995 for large employers (i.e., >50 covered employees) and January 1, 1996 for small employers. Currently the DOT regulations cover more than 12 million transportation workers nationwide.

Drug testing in the workplace has changed considerably over the last 20 years and the changes have improved the program. The development and scope of regulations related to testing have had an important effect not only to improve the accuracy and reliability of employee drug testing but also to establish the credibility of the testing process and the laboratories’ capabilities to routinely perform these tests. The stringent laboratory certification standards imposed on forensic drug-testing laboratories have influenced clinical laboratory medicine, with dramatic improvement over the last decade. A real concern is that the federal regulations may have become too rigid, precluding technological advances. The Substance Abuse and Mental Health Services Administration (SAMHSA), which was mandated oversight of workplace drug testing in 1992, has regularly modified regulations and, most recently, proposed new adaptations in technology in a broad sweeping proposal to include the testing of hair, sweat, and oral fluid in addition to urine specimens. It also proposes the use of on-site tests of urine and oral fluid at the collection site, the establishment of instrumented initial test facilities, and changes in operational standards.²

10.1.2 Incidence of Drugs in the Workplace

Good comprehensive statistics regarding drug use and testing incidence have not been developed. The National Household Survey (2003) shows that 19.5 million people over 12 years of age used drugs during the past month. Of these 54.6% used marijuana, 20.6% marijuana and other drugs, and 24.8% used other drugs. Use was predominately in the 14- to 29-year-old age group as follows: 10.9% (14–15), 19.2% (16–17), 23.3% (18–20), 18.3% (21–25), 13.4% (26–29), and 14.9% (all others).

The only comprehensive compilation of drug test data is published by Quest Diagnostics. Its Drug Testing Index is compiled semiannually. Quest Diagnostics is one of the largest providers of workplace drug tests performing more than 12 million tests annually. Its results are the best available statistical indication of trends in the field. Over the years the drug positivity rates have gone from a high in 1988 (13.6%) when drug-testing programs started to 4.5% in 2004. The number of positives has been relatively consistent since 1997 (5.0 to 4.5%); see Table 10.1.1. The positivity rates by drug category for the combined workforce for the last 5 years (2000 to 2004) is shown in Table 10.1.2. Updated revisions and more specific breakdowns of these statistics may be found on the Quest Diagnostics Web site www.questdiagnostics.com.

Table 10.1.1 Annual Positivity Rates for Combined U.S. Workforce (more than 7.2 million tests from January to December 2004)

Year	Drug Positive Rate
1988	13.6%
1989	12.7%
1990	11.0%
1991	8.8%
1992	8.8%
1993	8.4%
1994	7.5%
1995	6.7%
1996	5.8%
1997	5.0%
1998	4.8%
1999	4.6%
2000	4.7%
2001	4.6%
2002	4.4%
2003	4.5%
2004	4.5%

10.2 FEDERAL REGULATION OF WORKPLACE DRUG AND ALCOHOL TESTING

10.2.1 An Overview of the Mandatory Guidelines for Federal Workplace Drug Testing Programs

Donna M. Bush, Ph.D., DABFT

Drug Testing Team Leader, Division of Workplace Programs, Center for Substance Abuse Prevention, Substance Abuse and Mental Health Services Administration, Rockville, Maryland

10.2.1.1 History

“The Federal Government, as the largest employer in the world, can and should show the way towards achieving drug-free workplaces through a program designed to offer drug users a helping hand.” These words are part of President Reagan’s Executive Order (EO) Number 12564,¹ issued September 15, 1986, which served to launch the Federal Drug-Free Workplace Program. This EO authorized the Secretary of Health and Human Services (HHS) to promulgate scientific and technical guidelines for drug testing programs, and required agencies to conduct their drug testing programs in accordance with these guidelines once promulgated. This Federal Drug-Free Workplace Program covers approximately 1.8 million federal employees. Of this total number, approximately 400,000 federal employees and job applicants work in health- and safety-sensitive positions identified as Testing Designated Positions, and are subject to urine drug testing.

The Supplemental Appropriations Act of 1987 (Public Law 100-71, Section 503) outlined the general provisions for drug testing programs within the federal sector, and directed the Secretary of the Department of Health and Human Services (DHHS) to set comprehensive standards for all aspects of laboratory drug testing. The authority to develop and promulgate these standards was delegated to the National Institute on Drug Abuse (NIDA), an institute within the Alcohol, Drug Abuse and Mental Health Administration (ADAMHA). Following the ADAMHA Reorganization Act (Public Law No. 102-321) in 1992, the authority for this oversight now resides within the Center for Substance Abuse Prevention (CSAP), Substance Abuse and Mental Health Services Administration (SAMHSA). The Division of Workplace Programs (DWP) in CSAP, SAMHSA, administers and directs the National Laboratory Certification Program (NLCP), which certifies laboratories to perform drug testing in accordance with the “Mandatory Guidelines for Federal Workplace Drug Testing Programs” (Guidelines). These Guidelines were first published by the Secretary of HHS in the *Federal Register* on April 11, 1988,² and were revised and published in the *Federal Register* on June 9, 1994³ and again on November 13, 1998.⁴ Another revision was recently published in the *Federal Register* on April 13, 2004, and now includes specific urine specimen validity testing (SVT) requirements.⁵ The intent of these Guidelines is to ensure the accuracy, reliability, and forensic supportability of drug and SVT results as well as protect the privacy of individuals (federal employees) who are tested.

Subpart B of these Guidelines sets scientific and technical requirements for drug testing and forms the framework for the NLCP. Subpart C focuses on specific laboratory requirements and certification of laboratories engaged in drug testing for federal agencies. The Guidelines cover requirements in many aspects of analytical testing, standard operating procedures, quality assurance, and personnel qualifications.

Requirements for a comprehensive drug-free workplace model outlined in the Guidelines¹⁻⁵ include:

1. A policy that clearly defines the prohibition against illegal drug use and its consequences
2. Employee education about the dangers of drug use

3. Supervisor training concerning their responsibilities in a Drug-Free Workplace Program
4. A helping hand in the form of an Employee Assistance Program for employees who have a drug problem
5. Provisions for identifying employees who are illegal drug users, including drug testing on a controlled and carefully monitored basis

Several different types of drug testing are performed under federal authority. These include job applicant, accident/unsafe practice, reasonable suspicion, follow-up to treatment, random, and voluntary testing.

Under separate authority and public law, the U.S. Departments of Transportation (DOT) also conducts a similar Drug-Free Workplace Program that applies to more than 250,000 regulated industry employers who employ more than 12 million workers. The Nuclear Regulatory Commission conducts a similar Drug-Free Workplace Program that applies to about 104,000 employees working for its licensees. Both of these programs require that any drug testing performed as part of these Drug-Free Workplace Programs be conducted in a laboratory certified by the U.S. DHHS to perform testing in accordance with the scientific and technical requirements in the Guidelines.

In December 1988, the first ten laboratories were certified by DHHS through the NLCP to perform urine drug testing in accordance with the requirements specified in the Guidelines. As of July 2005, there are 49 certified laboratories in the NLCP. The largest number of laboratories certified at any one time was 91 in 1993. Even though there are fewer NLCP-certified laboratories today, the testing capability of the laboratories overall has greatly increased. This reflects the evolution of the business of drug testing, which includes laboratory chains and individual large-scale laboratories that can consistently and accurately test more than 10,000 specimens/day in accordance with the requirements of the mandatory Guidelines. In 2004, more than 6.5 million specimens were tested under federal requirements.

10.2.1.2 Specimen Collection

It is important to ensure the integrity, security, and proper identification of a donor's urine specimen. The donor's specimen is normally collected in the privacy of a bathroom stall or other partitioned area. Occasionally, a donor may try to avoid detection of drug use by tampering with, adulterating, or substituting their urine specimen. Precautions taken during the collection process include, but are not limited to the following:

1. Placing a bluing (dye) agent in the toilet bowl to deter specimen dilution with toilet bowl water
2. Requiring photo identification of the donor to prevent another individual from providing the specimen
3. Requiring the donor to empty his or her pockets and display the items to the collector
4. Requiring the donor to wash his or her hands prior to the collection
5. Collector remaining close to the donor to deter tampering, adulterating, or substituting by the donor
6. Taking the temperature of the specimen within 4 min of collection

A label that is made of tamper-evident material is used to seal the specimen bottle, and a standardized Federal Custody and Control Form (CCF) is used to identify the individuals who handled the specimen, for what purpose, and when they had possession of the specimen.

The entire collection process must be able to withstand the closest scrutiny and challenges to its integrity, especially if a specimen is reported positive for a drug or metabolite, substituted, adulterated, or invalid.

To ensure uniformity among all federal agency and federally regulated workplace drug testing programs, the use of an OMB-approved federal CCF is required. Based on the experiences of using the current federal CCF for the past several years, SAMHSA and DOT initiated a joint effort to develop a new federal CCF that was easier to use and that more accurately reflected both the

collection process and how results were reported by the drug testing laboratories. The federal CCF is a five-page carbonless document, with copies distributed to all parties involved in specimen collection, testing, and reporting.

Copy 1 is the Laboratory Copy and accompanies the specimen(s) to the testing laboratory; Copy 2 is the Medical Review Officer (MRO) Copy and is sent directly to the MRO; Copy 3 is the Collector Copy and is retained by the specimen collector for a period of time; Copy 4 is the Employer Copy and is sent to the Agency representative; Copy 5 is given to the donor when the collection is completed.

An image of Copy 1 is shown in Figure 10.2.1. The entire form, including instructions, may be viewed at <http://workplace.samhsa.gov>.

Briefly, the Instruction for Completing the Federal Drug Testing Custody and Control Form is as follows:

- A. The collector ensures that the name and address of the drug testing laboratory appear on the top of the CCF and the Specimen I.D. number on the top of the CCF matches the Specimen I.D. number on the labels/seals.
- B. The collector provides the required information in STEP 1 on the CCF. The collector provides a remark in STEP 2 if the donor refuses to provide his/her SSN or Employee I.D. number.
- C. The collector gives a collection container to the donor for providing a specimen.
- D. After the donor gives the specimen to the collector, the collector checks the temperature of specimen within 4 minutes and marks the appropriate temperature box in STEP 2 on the CCF. The collector provides a remark if the temperature is outside the acceptable range.
- E. The collector checks the split or single specimen collection box. If no specimen is collected, that box is checked and a remark is provided. If it is an observed collection, that box is checked and a remark is provided. If no specimen is collected, Copy 1 is discarded and the remaining copies are distributed as required.
- F. The donor watches the collector pouring the specimen from the collection container into the specimen bottle(s), placing the cap(s) on the specimen bottle(s), and affixing the label(s)/seal(s) on the specimen bottle(s).
- G. The collector dates the specimen bottle label(s) after they are placed on the specimen bottle(s).
- H. Donor initials the specimen bottle label(s) after the label(s) have been placed on the specimen bottle(s).
- I. The collector turns to Copy 2 (MRO Copy) and instructs the donor to read the certification statement in STEP 5 and to sign, print name, date, provide phone numbers, and date of birth after reading the certification statement. If the donor refuses to sign the certification statement, the collector provides a remark in STEP 2 on Copy 1.
- J. The collector completes STEP 4 (i.e., provides signature, printed name, date, time of collection, and name of delivery service), immediately places the sealed specimen bottle(s) and Copy 1 of the CCF in a leak-proof plastic bag, releases specimen package to the delivery service, and distributes the other copies as required.

DWP publishes a Urine Specimen Collection Handbook for Federal Agency Workplace Drug Testing Programs, available at <http://workplace.samhsa.gov>, which provides additional guidance to those who will be collecting federal employee urine specimens in accordance with the Guidelines.⁶

10.2.1.3 Specimen Testing

The procedures described in the Guidelines include, but are not limited to, collecting a urine specimen, transporting specimens to the laboratories, drug and validity testing of the specimen, evaluating test results by qualified personnel, specifying quality control measures within the labo-

OMAB No. 0930-0151

PRESS HARD - YOU ARE MAKING MULTIPLE COPIES

Figure 10.2.1 Copy 1 of federal CCF.

ratory, specifying record keeping and reporting of laboratory results to an MRO, and standards for certification of drug testing laboratories by SAMHSA.

The cornerstone of the analytical testing requirements specified in the Guidelines is the “two-test” concept: (1) an initial test is performed for each class of drugs tested and a drug(s) for creatinine, pH, and oxidizing adulterants; if an initial test is positive for drugs or outside defined limits for SVT, (2) a confirmatory test using a different chemical principle is performed on a different aliquot of the original specimen. Specifically, the initial test technology requires an immunoassay for drugs and colorimetric test for creatinine, pH, and oxidizing adulterants. The confirmatory testing technology requires gas chromatography/mass spectrometry (GC/MS) for drugs, and potentiometry using a pH meter, multiwavelength spectrophotometry, ion chromatography, atomic absorption spectrophotometry, inductively coupled plasma mass spectrometry, capillary electrophoresis, or GC/MS for SVT.

The initial test cutoffs as published in the Guidelines⁵ are as follows:

Drug Class	Cutoff (ng/ml)
Marijuana metabolites	50
Cocaine metabolites	300
Opiate metabolites	2000
Phencyclidine	25
Amphetamines	1000

The confirmatory test cutoffs as published in the Guidelines⁵ are as follows:

Drug	Cutoff (ng/ml)
Marijuana metabolite ^a	15
Cocaine metabolite ^b	150
Opiates	
Morphine	2000
Codeine	2000
6-Acetylmorphine ^c	10
Phencyclidine	25
Amphetamines	
Amphetamine	500
Methamphetamine ^d	500

^a delta-9-Tetrahydrocannabinol-9-carboxylic acid.

^b Benzoylcegonine.

^c 6-Acetylmorphine tested when the morphine concentration is greater than or equal to 2000 ng/ml.

^d Specimen must also contain 200 ng/ml amphetamine.

SVT for federal employee specimens collected under the Guidelines is required as of November 1, 2004. This includes, but is not limited to, determining creatinine concentration, the specific gravity of every specimen for which the creatinine concentration is less than 20 mg/dl, pH, and performing one or more validity tests for oxidizing adulterants. A much more complete discussion of specimen testing and reporting results can be found in the Guidelines.⁶

As part of an overall quality assurance program, there are three levels of quality control (QC) required of each certified laboratory:

1. Internal open and blind samples constituting 10% of the daily, routine sample workload (these are constructed by the laboratory as part of their daily testing protocols).
2. External open performance testing samples, which are distributed quarterly (these are prepared by the government under contract).
3. Double-blind QC samples, which constitute 1% of the total number of specimens submitted to the laboratory for analysis, not to exceed 100 per quarter; 80% of these samples are negative for drugs.
4. Federal agencies are required to procure and submit these samples from reputable suppliers.

10.2.1.4 Laboratory Result Reporting to and Review of Laboratory Results by an MRO

After accurate and reliable urine drug test results are completed by a SAMHSA-certified laboratory, the Guidelines require these results to be reported to an agency's MRO. As defined in the Guidelines, the MRO is a licensed physician responsible for receiving laboratory results generated by an agency's drug testing program who has knowledge of substance abuse disorders and who has appropriate medical training to interpret and evaluate an individual's positive test result together with the medical records provided to the MRO by the donor, his or her medical history, and any other relevant biomedical information. The MRO must contact the donor when the donor's specimen is reported by the laboratory as drug positive, adulterated, substituted, or invalid, and give the donor the opportunity to discuss the results prior to making a final decision to verify the test result. The donor is given the opportunity to request a retest when his or her specimen is reported as positive, substituted, or adulterated. The retest (i.e., an aliquot of the single specimen collection or Bottle B of a split specimen collection) is performed at a second certified laboratory, with specific procedures applied, depending on the results reported by the first testing laboratory.

A positive test result does not automatically identify an individual as an illegal drug user. The MRO evaluates all relevant medical information provided to him or her by the donor who tested positive. If there was a legitimate, alternative medical explanation for the presence of the drug(s) in the donor's urine, the test result is reported as negative to the employer; if there is no alternative medical explanation for the presence of drug(s) in the donor's urine, the MRO reports the result as positive to the agency/employer. Additional instruction and guidance for evaluating adulterated, substituted, and invalid test results for federal employee specimens is provided in the MRO Manual for Federal Agency Drug Testing Programs.⁷

It is also necessary that negative laboratory results be reviewed by an MRO. Laboratory results for double blind performance test samples (many of which are negative) are reported to the MRO in the same manner as results for donor specimens. In this manner, negative laboratory results are evaluated as part of ongoing quality control programs initiated prior to specimen submission to the laboratory.

10.2.1.5 Laboratory Participation in the National Laboratory Certification Program

Application

A laboratory applying to become part of the NLCP must complete a comprehensive application form, which reflects in detail each section of the Laboratory Information Checklist and General Laboratory Inspection Reports. Evaluation of this completed application must show that the laboratory is equipped and staffed in a manner to test specimens in compliance with the Guidelines' requirements in order for the laboratory to proceed with the initial certification process.

In essence, the Guidelines promulgate forensic drug testing standards for the evaluation of a specimen provided by a federal employee, on which critical employment decisions will be made. The processes that govern this testing are regulatory in nature, designed to ensure that this testing is accurate, reliable, and forensically supportable.

Performance Testing

As part of the initial certification process, the applicant laboratory must successfully analyze three sets of 25 samples (minimum), in a sequential order. The progress of this phase of the certification process is determined by the successful identification and quantification of analytes by the laboratory. If the first two sets of 25 samples are successfully completed, the third set of 25 samples is scheduled for receipt, accessioning, and analysis during the initial laboratory inspection site visit. As part of the maintenance certification process, each certified laboratory must successfully analyze a set of 25 samples (20 drug related and 5 SVT related) sent on a quarterly basis by the NLCP. There are five different types of samples developed by the NLCP to ensure accurate and reliable analyte identification and quantification for drugs and validity testing:

1. Routine samples, which may contain an analyte specified in the Guidelines, and are screened and confirmed in accordance with established cutoffs
2. Routine negative samples, which may contain a drug analyte specified in the Guidelines, but at a concentration less than or equal to 10% of cutoff
3. Routine plus samples, which may contain an analyte specified in the Guidelines and interfering and/or cross-reacting substances
4. Routine retest samples
5. Retest samples with interfering substances

For details on the evaluation of the performance test results, please refer directly to Section 3.18 of the April 13, 2004 Guidelines.⁵

Laboratory Inspection

The laboratory facility must be inspected and found acceptable in accordance with the conditions stated in the Guidelines and further detailed in the Laboratory Information Checklist, General Laboratory Inspection Report, Computer Systems Report, and Records Audit Report. Inspectors are trained by the NLCP staff (SAMHSA/DWP technical staff and their contractors) in the use of the detailed NLCP Laboratory Information Checklist and Reports, and the NLCP Manual for Laboratories and Inspectors.

Prior to the inspection, the laboratory is required to submit detailed information concerning its operations. This information is provided to the inspectors prior to the actual inspection. In this way, the inspectors become familiar with the laboratory operation prior to arrival. A brief description of each section completed by the laboratory follows:

- A. Instructions to Laboratory
- B. Laboratory Information — Physical aspects of the laboratory such as location, hours of operation, staffing, specimen testing throughput, and licenses
- C. Laboratory Procedures — Type of analytical equipment, calibration procedures, reagent kits, derivatives and ions monitored for each drug analyte, as well as similar information relating to validity testing

In addition, there are questions relating to certification and reporting of results, electronic reporting of results, as well as a description of the Laboratory Information Management System (LIMS).

In the past few years, a number of significant updates have been implemented in the NLCP inspection program. These improvements were the result of a careful review of the program experience over several years and also reflected the reality of market consolidation and growth that significantly increased the number of specimens tested under the Guidelines. This workload increase made it difficult for inspectors to review sufficient non-negative test results (i.e., positive, adulterated, invalid, and substituted) during the scheduled laboratory inspection. To address this issue, the NLCP

increased the number of inspectors and hours of inspections for some of the laboratory inspection categories. By increasing the number of inspectors, the percentage of non-negative test results reviewed by each inspection team was enhanced in the larger laboratories. The number of inspectors for Categories I and II remained unchanged. That is, a Category I inspection consisted of two inspectors (one checklist inspector and one data auditor) performing a 2-day inspection, and a Category II inspection consisted of three inspectors (one checklist inspector and two data auditors) performing a 2-day inspection. For the larger laboratories (i.e., Categories III to V) the NLCP increased the number of inspectors, and greatly enhanced the percentage of non-negative test results reviewed by the inspection teams. A Category III inspection now requires a team of four inspectors (two checklist inspectors and two data auditors, rather than the three inspectors previously inspecting this category of laboratory) conducting a 3-day inspection. A Category IV inspection has a team of five inspectors (two checklist inspectors and three data auditors) conducting a 3-day inspection. A new Category V inspection was established for laboratories with large workloads, usually testing more than 2000 regulated specimens per day. A Category V inspection has a team of nine inspectors (three checklist inspectors and six data auditors) conducting a 3-day inspection.

For those laboratories that use corporate LIMS not under the direct day-to-day observation and control of the responsible persons (RPs) of the laboratories that it serves, there will be a special inspection of the LIMS at the facility where the LIMS is located. This special inspection will be a 1-day inspection using two inspectors, with one a LIMS professional. Each corporate LIMS facility will undergo this inspection regardless of the number of laboratories that it serves. This new approach began in January 2005.

Historically, the NLCP has primarily focused the inspection on the procedures of the laboratory. The NLCP has now balanced that focus with an increased examination of the laboratory's forensic product. To accomplish this, a major audit component has been incorporated into NLCP inspections. To facilitate these audits, HHS requires each laboratory to submit a list to the NLCP staff of the non-negative (i.e., drug positive, adulterated, invalid, substituted, and rejected for testing) primary specimens and split specimens reported for a 6-month period prior to an inspection. Specific guidance on the format and information to be included on the list is provided to the laboratories. For each of the following specimen categories, the laboratory must submit a *separate* spreadsheet in a workbook to the NLCP:

1. Positive for delta-9-tetrahydrocannabinol-9-carboxylic acid
2. Positive for benzoylecgonine
3. Positive for opiates (morphine, codeine, and/or 6-acetylmorphine)
4. Positive for amphetamines (amphetamine and/or methamphetamine and *d*-methamphetamine if performed)
5. Positive for phencyclidine
6. Adulterated
7. Invalid test
8. Substituted
9. Rejected for testing

NLCP technical staff direct the laboratory to make available all the batch data and documentation for a selected number of those non-negative and split specimen test results to facilitate review by the inspectors. A specific number of non-negative specimens (NNS) are identified for in-depth review consisting of all analytical test records and chain of custody documentation. The number of NNSs selected for this in-depth information review is determined by the category of the laboratory and is as follows: 40 for Category I, 120 for Category II, 200 for Category III, 310 for Category IV, and 650 for Category V laboratories. Additionally, the same in-depth information review for 40 PT samples is conducted at each laboratory regardless of category.

As a key part of updating the NLCP laboratory inspection system, the inspector cadre was reviewed with the goal of using a smaller core group of inspectors, each of whom has committed

to participating in multiple inspections per year. This has significantly enhanced the consistency and uniformity in the NLCP inspection process. NLCP inspectors now are required to perform at least two to three inspections per year, to document active participation in forensic toxicology/workplace drug testing/regulated drug testing, and to attend mandatory NLCP inspector training on an annual basis.

The document previously known as the Laboratory Inspection Checklist was reorganized into two documents, from which two reports are generated by the inspection team. These two reports are the General Laboratory Inspection Report and the Records Audit Report. There were also some significant changes in the roles and configurations of NLCP inspection teams that represent the combined observations of the individual team members. Although each inspector does not complete a separate checklist, all team members tour the laboratory and participate in documenting/verifying any checklist deficiencies.

Inspectors assigned to the roles of “Lead Inspector” and “Inspector” use the General Laboratory Inspection Report to inspect the laboratory’s current standard operating procedures (SOP) and forensic operations and may aid in the review of the NLCP PT records, and method validation. The Lead Inspector has the responsibility to finalize and submit the team’s summary General Laboratory Inspection Report to RTI, Research Triangle Park, NC, the contractor currently handling the technical and logistical aspects of the National Laboratory Certification Program for SAM-HSA/HHS. Inspectors assigned to the roles of “Lead Auditor” and “Auditor” use the Data Audit Inspection Report and review a number of non-negative test results (i.e., positive, adulterated, invalid, and substituted), NLCP PT records, and method validation records. The Lead Auditor has the responsibility to finalize and submit the team’s summary Data Audit Inspection Report and NNS Review List to the NLCP.

The checklist inspector(s) review and document all aspects of forensic urine drug testing processes and procedures at that laboratory for program review and evaluation for compliance with the minimum standards of the Guidelines. The lead checklist inspector prepares a summary report reflecting the 12 sections of the inspection checklist and one section of the Computer System checklist reviewed during their site visit along with an Inspection Evaluation Summary. A brief description of each section follows:

- D. Chain of Custody — Assesses laboratory practices to verify specimen identity, maintain specimen integrity, secure specimens, and maintain chain of custody during specimen receiving/accessioning, aliquoting, initial drug testing, SVT, confirmation testing, and specimen and aliquot disposal
- E. Accessioning — Assesses laboratory practices to accept or reject specimens, evaluate specimen integrity, handle split specimens, maintain specimen integrity
- F. Security — Assesses laboratory practices to control and document specimen and record access
- G. Quality Control Materials and Reagents — Assess laboratory practices to prepare or procure and verify drug or SVT QC samples, properly identify them, and establish acceptable performance limits
- H. Quality Assurance: Review of QC Results — Assess laboratory practices to review control results so as to detect assay problems
- I. Equipment and Maintenance — Assess laboratory practices for checking and maintaining all laboratory equipment
- J. Specimen Validity Tests — Assess laboratory practices for handling of aliquots of specimens during validity testing, performing initial and confirmatory testing as required (at a minimum a test for creatinine, pH, and oxidizing adulterant on all specimens), applying appropriate cutoffs, analyzing appropriate QC samples for both initial and confirmatory testing as required
- K. Initial Drug Tests — Assess laboratory practices to analyze specimens with specific immunoassay methods and analyze appropriate QC samples
- L. Confirmatory Drug Tests — Assess laboratory practices to analyze specimens with appropriate GC/MS procedures and analyze appropriate QC samples
- M. Certification and Reporting — Assess laboratory practices to report negative and non-negative results to the MRO with both the federal CCF, and electronically if so desired

- N. Standard Operating Procedures, Procedures Manual — Assess laboratory procedure manual for content, comprehensiveness, agreement with day-to-day observed operations of the laboratory, determine availability to staff as a routine reference, and any modifications made to reflect changes in current practice in the laboratory
- O. Personnel — Assess qualifications of the RP, scientists who certify the accuracy and reliability of results, and supervisory staff; assesses staffing adequacy of these personnel in relationship to the number of specimens analyzed
- P. Laboratory Computer Systems — Assess laboratory policies and procedures for the validation and security of the LIM system, the handling of electronic records and reports, the ability to provide audit trails, monitoring the LIM system, and responding to incidents and providing disaster recovery, as well as documenting the qualifications of the LIMS personnel

The auditor(s) extensively review the laboratory's chain of custody documentation, analytical data, and reported results for non-negative specimens (i.e., positive, adulterated, substituted, invalid, rejected for testing) reported in the defined 6-month period (1 month prior to the last inspection to 1 month prior to the current inspection). The lead auditor prepares a summary report reflecting the four sections of the records audit report along with an Inspection Evaluation Summary and Summary of Issues. A brief description of each section follows:

- R. Specimen Records — Review and evaluate specimen records for completion of chain of custody documents, for identity of specimens, calibrators and controls, for the individuals performing and reviewing the testing, evidence that the certifying scientists who reported the results to the MROs reviewed all appropriate information
- S. Method Validation, Periodic Re-Verification — Review and evaluate revised test methods, and both SVT and confirmatory drug assays for periodic re-verification for levels of detection, linearity, and specificity
- T. NLCP Performance Test Records — Review and evaluate the NLCP PT records to determine if they support the reported results and if all remediation to PT errors was taken and acceptable
- U. Reports — Review and evaluate non-negative specimen reports, both hard copy and electronic, to determine if they are in accordance with NLCP guidance

The laboratory's first (initial) inspection is performed by two NLCP-trained inspectors. Prior to their arrival at the laboratory site, the inspectors are provided copies of the information supplied by the laboratory concerning its operations, its standard operating procedures, and its testing procedures.

The inspectors complete sections of the checklist similar to those completed by the inspection team for a maintenance inspection and submit the completed document to the NLCP. A summary, or critique, is prepared from the report by an individual independent of that laboratory's inspection. The items in the critique are then evaluated for compliance with the minimum requirements of the Guidelines. It is necessary that a laboratory's operation be consistent with good forensic laboratory practice. Once all requirements are met, the laboratory is certified by the Secretary, DHHS, as being able to perform drug testing of federal employees' specimens in compliance with the Guidelines. A letter is sent to the laboratory conveying its certification in the NLCP.

Then, 3 months after its initial certification, the laboratory is again inspected, with a broadened focus, now evaluating both practice and the results reported by the laboratory. A critique developed from the individual checklist and audit reports is developed by an individual independent of that laboratory's inspection. The issues in the critique are then evaluated for compliance with the minimum requirements of the Guidelines. It is necessary that a laboratory's operation be consistent with good forensic laboratory practice. If all requirements are met or there are minor easily correctable deficiencies, the inspection critique is sent to the laboratory. A cover letter may also be included, which outlines issues that must be addressed within a defined timeframe. After successful completion of this inspection, a 6-month cycle of site inspections begins. The number of inspectors sent to the laboratory for an inspection depends on the resources necessary to adequately evaluate the laboratory's operation. These resources are allocated based on the

laboratory's personnel involved in accessioning and certification, the number of specimens performed under the laboratory's certification, and the number of non-negative specimens reported by the laboratory.

During the maintenance phase of a laboratory's certification, if all requirements are met or there are minor easily correctable deficiencies, the inspection critique is sent to the laboratory. A cover letter may also be included, which outlines issues that must be addressed within a defined time frame. A laboratory continues its certified status as long as its operation is in compliance with the Guidelines and consistent with good forensic laboratory practice. Since participation in the NLCP is a business decision on the part of a laboratory and is voluntary, a laboratory may choose to withdraw from the NLCP. Upon such voluntary withdrawal from the NLCP, a laboratory must inform its clients that it is no longer certified in the NLCP and cease to advertise itself as an NLCP-certified laboratory.

Suspension of Certification

If significant deficiencies in the laboratory's procedures are found, an evaluation of these deficiencies is performed by the NLCP, the program staff in the DWP, and the Office of the General Counsel. A report is prepared for the Director, DWP. If it is determined that there is imminent harm to the government and its employees, action may be taken by the Secretary to immediately suspend the laboratory's certification to perform drug testing of federal, federally regulated, and private sector specimens tested in accordance with the Guidelines. The period and terms of suspension depend on the facts and circumstances of the suspension and the need to ensure accurate and reliable drug testing of federal employees.

Revocation of Certification

Several factors may be considered by the Secretary in determining whether revocation is necessary. Among these are (1) unsatisfactory performance of employee drug testing, (2) unsatisfactory results of performance testing and/or laboratory inspections, (3) federal drug testing contract violations, (4) conviction for any criminal offense committed incident to operation of the laboratory, and (5) other causes that affect the accuracy and reliability of drug test results from that laboratory.

10.2.1.6 Conclusion

Illicit drug use and abuse continues to affect safety and security in the American workplace. Data from the 1995 National Household Survey on Drug Abuse⁸ reveal that there were 12.8 million current (or past month) users of illicit drugs. Since that time, there has been an increase in drug use and abuse. In 2003, the last year for which this report is available,⁹ the number of individuals, 12 or older, indicating current drug use was 19.4 million individuals.

Tragic events serve as examples of how drug abuse in the workplace can affect society and cause long-term environmental and economic consequences. Examples of such tragedies where substance abuse in the workplace was responsible for death and destruction include the 1986 railroad accident in Chase, MD, the 1991 subway accident in New York City, and the 1989 environmental disaster in Prince William Sound, AK, caused by the grounding of the *Exxon Valdez* oil tanker.

10.2.2 The Department of Transportation's Workplace Testing Program

Kenneth C. Edgell, M.S.

Past Director (2001–2004), Office of Drug and Alcohol Policy and Compliance, U.S. Department of Transportation, Washington, D.C.

The Department of Transportation (DOT) oversees the largest drug- and alcohol-testing program in the country. The DOT rules affect more than 12 million transportation employees across the U.S. The program also has international impact in that all motor carriers and some railroad workers whose work brings them into the U.S., either from Canada or Mexico, are subject to the same testing requirements as their American counterparts.

The overall responsibility for management and coordination of the DOT program resides with the Office of the Secretary of Transportation (OST), an Executive Cabinet position appointed by the president. Compliance and enforcement within the different transportation industries are the responsibility of the DOT agency that has regulatory authority over the particular industry. Those DOT agencies are the Federal Aviation Administration (FAA), Federal Motor Carrier Safety Administration (FMCSA), Federal Railroad Administration (FRA), Federal Transit Administration (FTA), and Pipeline and Hazardous Materials Safety Administration (PHMSA).

Safety has been the highest priority for the Secretary of Transportation since Congress established the department in 1966. One of the means used by the Secretary to ensure DOT maintains the highest degree of safety possible is to subject transportation workers to drug and alcohol testing. The workers who are tested have direct impact on the safety of the traveling public or the safety of those potentially affected by the transportation of hazardous products, such as gas and oil pipeline operations. Any worker, who has a positive test, or other drug and alcohol violation, becomes ineligible to continue performing the duties of his or her safety job. In order for the individual to return to a safety job in transportation, that person must satisfactorily complete certain DOT return-to-duty requirements.

Since the outset of the DOT program, there have been a number of legal challenges from those who oppose drug testing. However, because safety is its sole reason for existing, court decisions have allowed the testing to continue without any major setbacks. The Supreme Court, in fact, found a compelling government need “in an industry that is regulated pervasively to ensure safety.”¹ So, the program continues. As might be expected, most states that have developed statutes regarding nonregulated testing have referred to the DOT program as the standard of practice they would also follow.

10.2.2.1 Background

The Department of Transportation drug and alcohol testing rules were an outgrowth of a highly visible and tragic transportation accident that occurred in 1987. The investigation of the accident revealed that employees in safety jobs, regulated by DOT (in this case train crew members), admitted using marijuana and alcohol prior to the accident. In response to the findings of the accident investigation, Senators Earnest Hollings (D-SC) and John Danforth (R-MO) sponsored legislation requiring drug and alcohol testing in the rail, aviation, and trucking industries. DOT, feeling the obvious impact of the accident and the duty to respond to the public, did not wait for the passage of the bill, but instead implemented drug testing under its own authority in 1989.

The action of DOT appeared to have been insightful in the years to follow. In August 1991, another deadly transportation accident occurred. Barely 2 months later, the Hollings-Danforth bill, which had been stymied in Congress for more than 4 years, was passed and signed into law by then-President George H.W. Bush. That legislation, cited as the “Omnibus Transportation Employee Testing Act of 1991” (OTETA),² required drug and alcohol testing of employees occupying safety-sensitive jobs in the transportation industries of aviation, trucking, railroads, and mass transit “in the interests of safety.” While the gas and oil pipeline industry and the U.S. Coast Guard’s (USCG) maritime industry were not mentioned in OTETA, testing within those industries also began, and continues, under the authority granted to DOT as a government agency with regulatory responsibility.

Like most laws, OTETA provided a general overview of what Congress expected to occur. It provided high-level instructions on who would be tested and for what reasons, how the tests would be conducted, and what would happen if and when someone tested positive. With that basic guidance, the statute put the burden of prescribing the remainder of the detail (i.e., the regulations) on the Secretary of Transportation. To fully meet the requirements of OTETA — and develop regulations that were as consistent as possible across all of DOT — the Secretary established the Office of Drug and Alcohol Policy and Compliance (ODAPC) to manage the development effort for workplace drug and alcohol testing.

ODAPC is a “small” office (staffing has never exceeded more than ten people) whose mission is to ensure that the drug and alcohol testing policies and goals of the Secretary are developed and carried out in a consistent, efficient, and effective manner within the transportation industries for the ultimate safety and protection of the traveling public. This is accomplished through program review, compliance evaluation, and the issuance of consistent guidance material for DOT Operating Administrations (OAs) and for their regulated industries. The director of ODAPC is a “political appointee,” in that as the administration changes, the director changes; the staff are career employees. Information about this office, along with the most current updates of program documents, can be found at the ODAPC Web site: www.dot.gov/ost/dapc/.

49 CFR Part 40, the “Procedures for Transportation Workplace **Drug and Alcohol Testing** Programs,”³ was developed by ODAPC. With this document, DOT set the standard by which all of its required drug and alcohol testing would be conducted. Such a standard assures that whether the employee is an airline pilot, truck driver, or railroad engineer, their drug and alcohol tests are conducted and reviewed using the same procedures. This regulation also sets the criteria that must be met before a person can return to safety-sensitive work after a drug or alcohol violation. Better

Table 10.2.1 Number of Federally Regulated Employers and Employees Subject to Testing

Industry	Government Agency	No. Employers	No. Employees
Aviation	FAA	7,200	525,000
Highway	FMCSA	650,000	10,941,000
Railroad	FRA	650	97,000
Transit	FTA	2,600	250,000
Pipeline	PHMSA	2,450	190,000
Maritime	USCG ⁵	12,000	132,000
Totals		674,900	12,135,000

known simply as “Part 40,” this regulation, or rule (the terms are used interchangeably) has become the standard for drug and alcohol testing in the workplaces across the U.S. ODAPC is responsible for providing any authoritative interpretations, if and when they are necessary, on Part 40.

In 1994, also in response to OTETA, six agencies (or “modes,” as they are known) within DOT also published testing regulations.⁴ These regulations covered who would be subject to drug and alcohol tests, when and why those tests would occur, and what responsibilities the transportation employers would bear in ensuring that the program was implemented properly. By the end of calendar year 2005, the scope of DOT testing covered approximately 12.1 million transportation workers (Table 10.2.1). It is estimated that out of this total population about 7,000,000 drug tests are conducted each year under DOT authority. This figure represents approximately 20% of the drug tests conducted in this country on an annual basis. The remaining 80% of the testing falls under “non-regulated” status, where companies of their own volition, not due to any government mandate, conduct tests. The number of alcohol tests conducted each year under DOT authority is far less than the number of drug tests; this number could be as little as 1,000,000 tests per year.

10.2.2.2 DOT Relationship with Health and Human Services

DOT drug testing follows the guidelines established by the Department of Health and Human Services (HHS). HHS was tasked⁶ during the Reagan Administration’s “War on Drugs,” to develop standards for conducting drug tests on federal employees who occupied positions of a safety- or security-related nature. Ultimately, HHS determined which drugs to test for and how laboratories should conduct the tests, including what cutoffs to use. HHS also established specific standards for certifying the laboratories to conduct drug tests for federal agencies. This material is published in an oddly titled regulation called the “Mandatory Guidelines.”⁷ More detail on the content of the HHS Guidelines can be found in elsewhere in this volume (see Section 10.2.1).

OTETA required DOT to “develop requirements that, for laboratories and testing procedures for controlled substances, incorporate the Department Health and Human Services scientific and technical guidelines dated April 11, 1988, and any amendments to those guidelines, including mandatory guidelines.” With that direction, DOT has taken most of the testing requirements contained in the HHS Guidelines, either by reference or by actually repeating the language, and incorporated them into Part 40 for those entities subject to DOT rules. This approach may seem a little repetitious, but it does allow those having to implement the programs not to have to maintain proficiency with two sets of drug testing rules issued by two government agencies.

The DOT drug-testing program is a laboratory-based urine-testing program, exclusively. While much ado was made of an “alternative specimen” proposal issued by HHS in 2004, which proposed allowing federal agencies to collect and test specimens other than urine (i.e., hair, oral fluid, and sweat), those specimens are not allowed for use under the DOT rules. Neither is any sort of “on-site” test. In fact, the HHS proposal does not apply to DOT.

For the record: Regardless of what conclusion HHS comes to with respect to “alternative specimens,” the DOT drug test program will not change until DOT issues a change to its rule — 49 CFR Part 40. Changing any government rule takes time and includes a public notice that seeks public comment. Prior to issuing a final rule, DOT will publish a Notice of Proposed Rulemaking (NPRM). (The NPRM is the document that will solicit public comment.) Complicated rulemaking, which would be the case if additional specimens were required for use by the DOT program, could take several years to finalize. Bottom line: Any utilization of alternative specimens in DOT drug testing is uncertain at this time. It may be an appropriate subject for a future edition of this text.

The remainder of this section provides a general summary of Part 40. For further understanding or more detailed information on a particular subject, especially for the purposes of trying to implement a DOT program, the reader should obtain a copy of the rule. It is written in what the government refers to as “plain language,” rather than gobbledygook, a style of writing more reminiscent of past federal offerings. The regulation is divided into functional sections and, while somewhat lengthy, is fairly easy to follow and understand.

10.2.2.3 Program Responsibility

The responsibility to assure that drug and alcohol testing is carried out according to the requirements of DOT lies with the transportation employers. Sometimes referred to as an “unfunded mandate,” the U.S. Congress, through the OTETA statute, mandated drug and alcohol testing for certain transportation industries, and instructed the Secretary of Transportation to develop the rules under which each industry must abide. However, neither DOT nor any of its agencies provides funding to transportation employers to offset any of the program costs. The DOT rules instruct transportation employers to implement this very comprehensive program and then hold the employers responsible for compliance. Employers are expected to absorb the costs; the benefit is a safer workplace.

Transportation employers are free to contract out any portion of the drug and alcohol testing program functions; however, employers cannot outsource their compliance responsibilities. *Service agents* is the term given to those who contract directly or indirectly with employers to accomplish the tasks set forth in DOT rules. Service agents include collectors, laboratories, medical review officers (MROs), breath alcohol technicians, consortia/third party administrators, and substance abuse professionals.

10.2.2.4 Safety-Sensitive Employees

OTETA required each DOT administration to specify those under its regulatory purview who are subject to testing. These individuals occupy positions known as “covered functions,” or, more universally, as “safety-sensitive” positions (Table 10.2.2). A person who occupies a safety-sensitive job and performs its functions, whether on a full-time, part-time, or intermittent basis, is subject to testing.

Table 10.2.2 Government Agencies and Safety-Sensitive Job Positions

Industry (Mode)	Safety-Sensitive Job Positions
Aviation (FAA)	Flight crew members, flight attendants, flight instructors, air traffic controllers, aircraft dispatchers, maintenance personnel, and screening and ground security coordinator personnel
Highways (FMCSA)	Commercial motor vehicle operators
Railroads (FRA)	Hours-of-service employees (engine, train and signal services, dispatchers, and operators)
Mass Transit (FTA)	Vehicle operators, dispatchers, mechanics, and safety personnel (carrying firearms)
Oil and Gas Pipeline (PHMSA)	Pipeline operations and maintenance personnel, and emergency response personnel
Maritime (USCG)	Maritime crew members (operating a commercial vessel)

10.2.2.5 Reasons for Testing

The DOT drug-testing program is a deterrence-based program, testing for prohibited use of illegal drugs regardless of when the employee might use the drugs. The DOT alcohol-testing program is more a fitness-for-duty program; testing for prohibited use of a legal substance in and around the time a person is working. Drug tests may be conducted at any time the employee is at work, while alcohol tests are only conducted prior to, during, or just after the performance of safety-sensitive functions. OTETA requires DOT to have specific categories of testing, or “reasons for test.” There are six testing categories: pre-employment, post-accident, random, reasonable suspicion, return-to-duty, and follow-up.

Pre-employment tests may be conducted before an applicant is hired or after an offer to hire. These tests must be conducted prior to the actual first-time performance of the individual’s safety-sensitive functions. Pre-employment tests are also required when employees transfer to a safety-sensitive position from a non-safety-sensitive position within the same company. All DOT modes require new employees to take (and pass) a pre-employment drug test before they begin work. Pre-employment alcohol tests are authorized, but not mandated by all modes. DOT leaves the decision to conduct pre-employment alcohol tests to each individual transportation employer.

Post-accident testing is conducted after qualifying accidents or where the performance of the employee could have contributed to the accident. Each administration determines what “qualifying” means, with respect to an accident within its particular industry. Obviously, aviation accidents are drastically different from highway accidents. Referencing the rule that corresponds to one of the six administrations would be necessary to determine the criteria for a qualifying accident and subsequent requirements for testing. Contributing to an accident could be seen, for example, in a citation given to a driver by law enforcement after a moving traffic violation. All modes do require that post-accident alcohol tests be conducted within 8 h, and post-accident drug tests be conducted within 32 h of the occurrence of the accident.

Random tests are conducted on a random, unannounced basis. Random testing rates are established in a consistent manner at the beginning of each year, but can be different from mode to mode. Each administration sets the annual random testing rate, one for drugs and one for alcohol, based on the industry’s respective random positive rate for the previous year. There are two possible annual rates for random drug testing — 25 or 50%; random alcohol testing has three possible rates of testing — 10, 25, and 50%.

If an industry has a random drug-positive rate of 1% or less for 2 consecutive years, the administrator may reduce the random testing rate to 25% per year for that industry. If the random positive rate is greater than 1% for any year, the random testing rate must move back to 50% per year. Like random drug testing, a random alcohol testing rate is calculated for each industry based on that industry’s positive rate for the past 1 to 2 years. If the industry’s positive rate is less than 0.5% for 2 consecutive years, the modal administrator can set the resulting alcohol testing rate at 10%. Between 0.5 and 1% for 2 consecutive years, the administrator can set the rate at 25%. When the industry positive rate goes above 1%, the random testing rate is set at 50%. A mode must hold a random positive rate within the above ranges for 2 consecutive years in order for the testing rate to be reduced; a 1-year increase returns the industry to the next higher testing rate. Employees in the pipeline industry, under PHMSA, and employees in the maritime industry, under USCG, are not subject to random alcohol testing. The best explanation for this difference is that neither industry was mentioned in OTETA.

Reasonable suspicion testing is conducted when a supervisor, previously trained in the signs and symptoms of drug abuse and alcohol misuse, observes behavior or appearance that is characteristic of drug or alcohol abuse of the employee. The test must be based on observations that are specific, contemporaneous, and articulable. A rumor of “a big party” over the weekend is not reason enough to conduct a reasonable suspicion test.

Return-to-duty and *follow-up* testing is conducted when an individual, who has a drug or alcohol violation (e.g., positive test), returns to the workplace to resume his or her safety-sensitive work. Initially, a return-to-duty test is given. After passing the return-to-duty test, the employee is eligible to return to safety work. Upon returning to work, the person will be placed back in the company's random testing pool. At the same time, the person must also be subject to unannounced follow-up testing to be conducted at least six times within the first 12 months of returning to work.

10.2.2.6 Consequences of a Drug or Alcohol Violation

All workers committing a violation of the DOT drug or alcohol rules must be removed immediately from their safety-sensitive job and are ineligible to return until they satisfactorily complete the DOT return-to-duty requirements. A DOT drug or alcohol violation includes:

- Alcohol tests with a result of 0.04 or higher alcohol concentration
- Verified positive drug tests
- Refusals to be tested (including verified adulterated or substituted drug test results)
- Other violations of DOT agency drug and alcohol testing regulations (such as, using or possessing alcohol or illicit drugs while on duty, or using alcohol within 4 h–8 h for flight crews and flight attendants — of reporting for duty, or using alcohol within 8 h after an accident or prior to a post-accident test being conducted, whichever comes first)

10.2.2.7 Specimen Collections

DOT has established a specific set of procedures for collecting a urine specimen. Precautions are built into the process to help ensure the control and integrity of the collection. The detail that DOT has devoted to collecting the specimen will serve to minimize the collection errors and maximize the probability that the employer will be able to rely on the test result, regardless of its outcome. DOT has built the model system, but it is the individual diligence of each collector upon which that system relies. Obviously, a problem occurring during the collection has the potential to “ripple” and affect the test outcome.

A DOT urine specimen must be collected using a standard collection kit, documented with a standard form, and conducted by a trained collector. All DOT specimens are collected as “split specimens.” The standard kit consists of a single-use collection container that has an attached temperature strip for reading the urine temperature, two sealable plastic bottles for the “split specimens,” a leak-resistant plastic bag with two separate pouches (one for the bottles and the other for the collection paperwork), absorbent material, and a shipping container to protect the specimen during transit to the laboratory (Figure 10.2.2).

The standard form for all DOT collections is the Federal Drug Testing Custody and Control Form, or CCF. The CCF is a five-part form. DOT requires the same form for collections as is used within the federal program, under the purview of HHS. Figure 10.2.1 in the previous section presents an illustration of the CCF.

The collector is the person who is in charge of and assists with the collection and has been trained under the provisions of DOT's Part 40 and the DOT Urine Specimen Collection Guidelines,⁸ written by ODAPC. Collectors need to be trained prior to collecting their first specimen.

All DOT collections allow the donor to provide the specimen in the privacy of a bathroom stall unless there is a suspicion of tampering, on the part of the donor, or preexisting conditions allow an exception (i.e., return-to-duty and follow-up). The exception would be to conduct the collection under direct-observation procedures, whereby a same-sex collector watches the specimen flow directly from the donor's body and into the collection cup.

DOT has broken down the specimen collection procedure into some 23 different steps in the Collection Guidelines. In general, the donor will present for a urine collection and provide the

Figure 10.2.2 Example of DOT Standard Urine Collection Kit.

collector with a form of identification that includes a picture ID. The collector will briefly explain the collection process to the donor emphasizing that, once the collection begins, the donor cannot leave the collection site until excused by the collector. DOT directs collectors to obtain a minimum of 45 ml of urine in one single void; 30 ml is for the primary specimen and 15 ml is for the “split” specimen. Generally collections take less than 15 min to complete.

Donors will be informed that their collection period will be extended up to 3 h in order to obtain the requisite volume of urine should the donor be unable to provide the full 45 ml in a single void. During the additional time period, the donor will be encouraged to drink up to 40 oz. of fluid. After 3 h, if the donor fails to provide the required amount, the collector will inform the donor’s employer. The employer must then send the employee for a physical examination. The finding of the examination must be that the individual has a current physical, or a pre-documented psychiatric, condition, or the final result will be deemed a “refusal to test.” This expanded collection, with the follow-on physical examination, is referred to as the “shy bladder” process.

During the instruction phase of the collection, the collector will also instruct the donor that the failure to follow any of the collector’s instructions could result in the collector stopping the testing process and informing the donor’s employer that the donor has “refused to test.”

The collection procedures include precautions to guard against possible tampering, such as toilet-water bluing and having donors empty their pockets to reveal any adulterating-type products. Donor are also required to wash their hands before entering the bathroom stall. When the donor presents the collector with the specimen, the collector will examine the specimen for signs of tampering and check the temperature to make sure it is within the acceptable range (90 to 100°F). Any attempt by the donor to adulterate the specimen, which is detected by the collector (e.g., a blue specimen), will result in a second collection to follow immediately. That collection will be conducted using the direct-observation procedures. Should the donor refuse to permit the same-sex, direct-observation collection to occur, the collector will stop the collection and inform the donor that the donor has refused to test. “Refusals to test” are final results of record, and are DOT violations.

Assuming that the collection has gone without incident, the collector will divide, or “split,” the specimen into two separate specimen bottles and seal and label both bottles with uniquely numbered tampering-evident labels that are an integral part of the CCF. This is an important step and must be witnessed by the donor. The CCF paperwork is completed with both the donor and collector filling out their specific sections, and then the split specimens and one copy of the CCF are placed in the leak-proof plastic bag, which is sealed and ready to be sent to the laboratory.

It is the responsibility of the collector to secure the specimens until they are sent to the laboratory. The final duty of the collector is to distribute the remaining copies of the CCF to the appropriate parties (i.e., MRO, collector, employer, and employee).

Even though DOT has developed specific training requirements for all collectors, with more than 7,000,000 collections each year, collection errors still occur. This is perhaps inevitable since the position of *collector* is still an entry-level position in most companies and, thus, subject to high turnover. Lack of proper training or training that is administered in a hurried manner is another cause of collection errors. However, any collector who makes an error that results in a test being canceled must be retrained.

10.2.2.8 Laboratory Testing

DOT makes exclusive use of laboratories certified under the HHS National Laboratory Certification Program. HHS publishes a listing of certified laboratories (each month in the *Federal Register*) of those meeting the criteria set forth in the HHS Guidelines. Currently, the vast majority of these laboratories are located in the U.S.; there are a couple in Canada, but none in Mexico. DOT follows HHS criteria for both drug testing and specimen validity testing. The criteria are specified in detail in Section 10.2.1 of this text. Therefore, only general references are made to DOT test criteria in this text section.

All laboratories receive, unpackage, and enter a DOT specimen into the testing process. This is called *accessioning*. All DOT specimens are tested for the five drugs of abuse: marijuana, cocaine, opiates, amphetamines, and phencyclidine. The drug panel has not changed since the outset of the program. DOT follows the protocols set up by HHS. Some of the test criteria, such as the cutoffs for initial or confirmation tests, have changed over the years. As testing technology advances and drug-use tendencies change, it is quite possible that similar changes may occur again in the future. It is also possible that additional drugs could be added to the test panel. However, such changes are not made without first being proposed to the public, in order that the public may comment on the recommendations, and then issuing a change to the HHS and DOT rules.

All DOT specimens also undergo “specimen validity” testing. This is a relatively new category of tests brought on in the late 1990s by attempts of individuals to beat the test by tampering with the specimen (e.g., adding a substance to the urine specimen in hopes of altering the test result).

Specimen validity testing (SVT) consists of measuring creatinine and specific gravity to detect a *diluted* or *substituted* specimen. pH is measured as one criterion established to detect an *adulterated* specimen. HHS has developed criteria to be used in testing for specific adulterants such as nitrites, chromates, surfactants, and other active chemical compounds. Substituted or adulterated specimen results are DOT rule violations and have the same weight as a positive test.

Sometimes neither drug testing nor SVT can produce a result that is conclusive. The laboratory may be able to determine only that the specimen has some abnormal reaction. Testing the specimen reveals that it has definitely not met criteria to be reported as negative, however, criteria are not met to call it positive, substituted, or adulterated. This result is classified as *invalid*. Most invalid test results are recollected using directly observed collection procedures.

All results fall into one of two categories: negative and non-negative. *Negative* specimens are those that prove to be negative for drugs and do not have any specimen-validity issues. Negative results may also show that the specimen was *dilute*. (Dilute specimen results are not violations; however, DOT allows employers to have a policy of recollecting specimens from employees who have dilute results.) Approximately 95% of all DOT specimens are negative. Negative results are reached in less (laboratory) time than non-negative results. DOT gives laboratories the authority to report negative results using only computer-generated reports.

Non-negative specimens are all other results — positive, substituted, adulterated, and invalid. Since some of these results will require that the employee be removed from his safety-sensitive job, and possibly terminated, DOT requires more documentation be included with these test reports.

The laboratory must also provide a copy of the corresponding CCF, generated at the time of the collection and completed by the certifying laboratory scientist who verifies the laboratory results, when the report is released.

DOT test results may only be reported to a physician who will review the drug test. This physician is called the Medical Review Officer. DOT prohibits laboratories from reporting results to anyone other than the MRO (e.g., consortia/third-party administrators, employers).

10.2.2.9 Medical Review Officer

The MRO has been designated by DOT as the “gatekeeper” of the drug-testing program. “MROs” are physicians (a doctor of medicine or osteopathy) who receive all drug test results and make determinations whether the employee has committed a drug violation (e.g., verified positive test result), while maintaining the confidentiality for the employee during an interview process. MROs are required to have knowledge and clinical experience in substance abuse disorders, to be trained on Part 40, and to pass a written examination. Chasing paperwork, listening to far-fetched stories as to why a person was positive or how the specimen became adulterated, and dealing with employers anxious to put people to work are all part of the MRO’s duties.

Laboratories *certify* drug test results, while MROs *verify* drug test results. The MRO receives all DOT drug test results directly from the laboratory. Employers or third-party administrators are not authorized to receive the drug test results or act as an intermediary to the MRO. Staff, under the supervision of the MRO, may assist with paperwork duties, establishing donor contact, and reporting results to employers. However, only the MRO can conduct the interview with the donor to determine if there is a legitimate medical explanation for the positive, substituted, or adulterated test result.

“Legitimate medical explanations,” while rare for these test results, are possible. Recognizing what is acceptable and what is not is subject-matter training for MROs in the DOT-required MRO training courses. Generally, such explanations are limited to prescriptions or medical procedures where drugs are introduced to the donor and can subsequently be verified by the MRO. Additionally, special studies may be set up to prove that the donor can naturally produce a substituted or adulterated urine specimen. To date, there has been one such case for the former (substituted specimen), but none for the latter (adulterated specimen). In fact, as of this writing, there is no known adulterant, introduced *in vivo*, that can interfere with a laboratory’s analytical procedure. All adulterants that have an effect on the analytical process or can be detected by laboratory analysis are introduced into the specimen cup — by the donor — *in vitro*.

When the MRO gets a result that is positive, substituted, adulterated, or invalid, the donor will be contacted and interviewed by telephone. Through the interview, if the MRO determines that there is a legitimate medical reason for the donor’s test result, the MRO has the discretion to “downgrade” the result (from positive) to negative and forward that result to the employer. The process devised by DOT gives the MRO latitude to downgrade the final result to negative and still provide a safety warning to the employer if the donor is using a medication that would medically disqualify the donor under agency rules or where continued use would pose a safety risk, even though the medication was obtained with a valid prescription.

For those individuals for whom the MRO determines that the reported result will be positive, substituted, or adulterated, the MRO will also provide the donor with the opportunity of having the split specimen tested at another HHS-certified laboratory. However, the employer will immediately remove the donor from the safety job being performed on the initial report by the MRO. If the split specimen result does not confirm the initial specimen result, the result reported to the employer will be canceled by the MRO — as if the test never occurred — and the donor will undergo a second collection where the process starts over from scratch. If the split confirms the initial result, which is what normally occurs, the employer and the donor are so notified.

MROs may also be called upon for consultation during the post-violation assessment process that the donor must undergo in order to return to the transportation workplace. MROs are encouraged

to cooperate with this part of the process, which usually involves providing only drug quantitations that may be helpful during the assessment. MROs may also be asked to assist the donor in obtaining test records from the laboratory that conducted the testing. DOT requires laboratories to interface with MROs, not donors. Donors are entitled to any records produced as a result of their drug test, and having the MRO act as the intermediary keeps it simple. Likewise, donors have access to MRO records, pertaining to their test, as well as laboratory records.

10.2.2.10 Alcohol Testing

OTETA mandated that alcohol tests be part of the dual-testing program. For the first time in the workplace setting, alcohol tests would be conducted alongside drug tests. This new territory presented especially difficult challenges for the DOT.

Alcohol, unlike the drugs that DOT tests for, is a legal substance. While it could not be tolerated in the safety-sensitive workplace, parameters had to be established for off-duty use occurring near the time when the employee would report for duty. Additionally, consideration needed to be given to the period after accidents, but prior to a test being conducted.

Originally the DOT interpreted OTETA language as requiring alcohol testing for all reasons-for-test: pre-employment, random, reasonable suspicion, post-accident, return-to-duty, and follow-up. The 1994 testing rules issued by DOT included requirements for all six test categories. Eventually, the 4th Circuit Court of Appeals ruled that pre-employment testing was problematic as a routine, mandated test. It was subsequently reverted back to DOT for resolution. DOT decided to “authorize” employers to conduct pre-employment alcohol tests as a condition of employment, and definitively modified the rules in 2001. Today, alcohol testing is authorized for pre-employment and mandated for other test reasons (except random testing) in the same manner as drug tests. Random alcohol tests are not required under PHMSA and USCG rules.

Personnel who conduct alcohol tests are called screening test technicians (STT) and breath alcohol technicians (BAT). Most of the tests are conducted by “BATs,” as they are called. Both

Figure 10.2.3 DOT Breath Alcohol Testing in process.

Figure 10.2.4 Example of Evidential Breath Testing device.

technicians need to be trained and only use instruments for the test that have been approved by DOT. All alcohol test devices approved for DOT use are certified by DOT's National Highway Traffic Safety Administration (NHTSA) and placed on a use approved listing,⁹ which is published in the *Federal Register*.

Alcohol tests (Figure 10.2.3), like drug tests, use a standard form and a specific set of procedures,¹⁰ both designed and developed by DOT. Unlike drug testing, when alcohol was mandated by OTETA, DOT did not have the luxury of following HHS guidelines — no other branch of the government tests for alcohol. Procedures for workplace alcohol testing had to be developed by DOT.

Alcohol tests, like drug tests, use a two-test procedure. The first test, or initial test, can use either breath or saliva testing devices, and may be non-evidential in nature. The second test can only use an Evidential Breath Testing (EBT) device (Figure 10.2.4). This device produces a printed record documenting all aspects of the test (e.g., time of test, specific device, breath alcohol concentration). Any individual who shows the presence of alcohol at a concentration of 0.02 or higher on the initial test must be subjected to a second test, or confirmation test. Prior to conducting the second test, the BAT will wait at least 15 min, but not more than 30 min, before proceeding. This 15-min waiting period allows any alcohol that may be in the person's mouth to dissipate. "Mouth alcohol" can be attributed to mouthwash or breath lozenges. The waiting period is precautionary to protect the person being tested. During this wait period, the BAT will also conduct an "air blank" on the EBT to show that the device does not contain any residual alcohol.

The result of the second test becomes the result of record. An alcohol concentration of 0.04 or higher is a DOT violation (e.g., similar to a positive drug test); an alcohol concentration between 0.02 and 0.039 is prohibited conduct, and the person cannot perform safety-sensitive work while testing within this range.

The services of an MRO, to review an alcohol test, are not required. The reason is that there is no legitimate medical explanation for alcohol in one's system. Alcohol is alcohol. Whether its source was from beer, whiskey, or mouthwash, the effect is still the same. The BAT will report the result immediately to the employer and the employer will respond by removing the person from duty.

10.2.2.11 Substance Abuse Professional

OTETA requires that an opportunity for treatment be made available to covered employees. In order to implement this mandate, an employer must refer any transportation worker, who has engaged in conduct prohibited by DOT drug or alcohol rules, for evaluation and treatment. Modeled

with the substance abuse profession in mind, the DOT rules require substance abuse professionals, or SAPs, to have certain credentials, possess specific knowledge, receive training, and achieve a passing score on an examination. There is also a continuing education requirement. The SAP Guidelines,¹¹ written by ODAPC, supplement Part 40.

The primary safety objective of the DOT rules is to prevent, through deterrence and detection, alcohol and controlled substance users from performing transportation industry safety-sensitive functions. The SAP is responsible for several duties important to the evaluation, referral, and treatment of employees identified through breath and urinalysis testing as positive for alcohol and controlled substance use, or who refuse to be tested, or who have violated other provisions of the DOT rules.

A SAP's fundamental responsibility is to provide a comprehensive face-to-face assessment and clinical evaluation to determine what level of assistance the employee needs in resolving problems associated with alcohol use or prohibited drug use. Following the evaluation, education and/or treatment is recommended, whereby the employee must demonstrate successful compliance in order to return to DOT safety-sensitive duty.

Prior to the employee's return to safety-sensitive duties, the SAP conducts a face-to-face follow-up evaluation with the employee to determine if the individual has demonstrated successful compliance with recommendations of the initial evaluation. This evaluation must be accomplished before an employer can consider the employee for return to safety-sensitive functions. Therefore, the evaluation serves to provide the employer with assurance that the employee has made appropriate clinical progress sufficient to return to work.

The SAP also develops and directs a follow-up testing plan for the employee returning to work following successful compliance, specifying the number and frequency of unannounced follow-up tests. If polysubstance use has been indicated, the follow-up testing plan should include testing for drugs as well as alcohol, even though a violation of both was not the original offense.

If the MRO is considered the "gatekeeper" in the drug-testing process, then the metaphor is equally appropriate for the SAP in the return-to-duty process.

10.2.2.12 Confidentiality and Release of Information

Part 40 is very clear about what information is to be generated, where it goes, and who is authorized to receive it. Beyond the Part 40 instruction, service agents and employers participating in the DOT drug or alcohol testing process are prohibited from releasing individual test results or medical information about an employee to third parties without the employee's specific written consent.

A "third party" is any person or organization that the rule (Part 40) does not explicitly authorize or require the transmission of information from in the course of the drug or alcohol testing process. "Specific written consent" means a statement signed by the employee agreeing to the release of a particular piece of information to a particular, explicitly identified, person or organization at a particular time. "Blanket releases," in which an employee agrees to a release of a category of information (e.g., all test results) or to release information to a category of parties (e.g., other employers who are members of a C/TPA, companies to which the employee may apply for employment), are prohibited by DOT.

Information pertaining to an employee's drug or alcohol test may be released in certain legal proceedings without the employee's consent. These include a lawsuit (e.g., a wrongful discharge action), grievance (e.g., an arbitration concerning disciplinary action taken by the employer), or administrative proceeding (e.g., an unemployment compensation hearing) brought by, or on behalf of, an employee and resulting from a positive DOT drug or alcohol test or a refusal to test. Also included are criminal or civil actions resulting from an employee's performance of safety-sensitive duties, in which a court of competent jurisdiction determines that the drug or alcohol test information sought is relevant to the case and issues an order directing the employer to produce the information. For example, in personal injury litigation following a truck or bus collision, the court could

determine that a post-accident drug test result of an employee is relevant to determining whether the driver or the driver's employer was negligent. The employer is authorized to respond to the court's order to produce the records.

DOT instructs employers and service agents to notify the employee in writing of any information released without the employee's written consent.

Lastly, release of DOT program information is not in conflict with the HHS Health Insurance Portability and Accountability (HIPAA) rules.¹² HIPAA rules do not conflict with the DOT drug and alcohol-testing program for employer and service agent responsibilities under Part 40 and operating administration drug and alcohol testing rules. Information may be generated and flow to its intended parties, as required by Part 40, without the employee signing a HIPAA-type consent.

10.2.2.13 Consortium/Third-Party Administrators

In the early days of the DOT testing program, the department believed that employers might pool their resources or band together to help each other accomplish the things the testing rules required. This did not happen. What did happen was that the DOT program created an entire "cottage industry" of *service agents*, including consortia/third-party administrators (C/TPA), and substance abuse providers, who contract directly or indirectly with employers to accomplish the tasks set forth in DOT rules. In short, a C/TPA will handle all of the administrative processes for an employer's testing program. The types of services typically offered by C/TPAs are:

- Urine collections, including permanent and mobile facilities
- Laboratory testing
- Random selections
- Background checks on new hires
- Policy and procedures
- Supervisory training
- Providing MRO test review and SAP referrals
- Maintaining records and preparing statistical data
- Assisting employers preparing for DOT audits

Employers are allowed to contract with C/TPAs (service agents) to get the job done. Service agents are obligated to do the work they have signed on to do as if they were the employer. However, even though the department has a method to rid the testing community of a "bad" service agent, the employer is still held responsible for the actions of the service agent.

10.2.2.14 Public Interest Exclusion

Service agents perform the bulk of drug and alcohol testing services for transportation employers. Employers, particularly small employers, necessarily rely on service agents to comply with their testing obligations. Employers are ultimately responsible for all aspects of the program. However, in good faith, they may hire a service agent who purposely does not comply with the rules. These employers often do not have the expertise in testing matters that would enable them to evaluate independently the quality, or even the regulatory compliance, of the work that service agents perform for them. Subpart R of Part 40 provides a mechanism to help ensure that service agents will be held accountable for serious noncompliance with DOT rules. The *public interest exclusion* (PIE) is based in concept on the existing DOT non-procurement suspension and debarment rule¹³ and permits DOT to suspend a service agent for willful noncompliance with the drug and alcohol testing rules. The mechanism, both for policy and resource reasons, is only used in cases of serious misconduct.

An employer's compliance with DOT regulations is largely dependent on its service agents' performance. If a service agent makes a serious mistake that results in the employer being out of compliance with a DOT rule, accountability must be addressed. The employer may be subject to

civil penalties from a DOT agency. The employer can be subject to litigation resulting from personnel action it took on the basis of the service agent's noncomplying services. Most importantly, the employer's efforts to ensure the safety of its operations may be damaged, e.g., as when an employee who apparently uses drugs is returned to duty because of a service agent's noncompliance.

The standard of proof in a PIE proceeding is "the preponderance of the evidence." There is no policy or legal basis apparent for raising this burden to the higher "clear and convincing evidence" level. A PIE could apply to all the divisions, organizational elements, and types of services provided by the service agent involved, unless the director limited the scope of the proceeding. Under some circumstances, affiliates and individuals could also be subject to a PIE. The intent of the PIE is to protect the public from the misconduct of an organization. As of mid-2006, the DOT had not suspended any service agents.

10.2.2.15 Conclusion

The history of the DOT drug- and alcohol-testing program is a relatively short one. The benefits of the last 10-plus years of program implementation are not fully known. However, data on illegal drug use by transportation employees, accidents related to use, and changes in attitudes about workplace safety and substance abuse are encouraging. The ultimate success of OTETA and the employer-based programs that it mandates will be measured over time in terms of lives saved, injuries prevented, and property losses reduced. OTETA is not a cure-all for safety problems or problem workers. Only everyday due diligence on the part of all safety workers will help in that area.

10.2.3 Drug Testing in the Nuclear Power Industry: The NRC Fitness-for-Duty Rules

Theodore F. Shults, J.D., M.S.

Chairman, American Association of Medical Review Officers, Research Triangle Park, North Carolina

10.2.3.1 Background

The private nuclear power generating industry in the U.S. is highly regulated. The primary federal regulator is the Nuclear Regulatory Commission (NRC). The NRC has a great deal of oversight, inspection responsibilities, safety analysis, and involvement in every aspect of the operation of a nuclear generating facility. The nuclear industry has been highly sensitive to the public safety aspect of its operations and recognizes that in addition to the fundamental engineering issues involved in maintaining the safe operation and security of a reactor and its fuel, a great deal of attention must be paid to the basic human performance issues as well. In this industry careful consideration is given to who has access to the facility, their background, their health and their behavior — particularly in respect to illegal drug use and alcohol abuse.

The rules that govern drug and alcohol testing in the nuclear industry are called the *Fitness-for-Duty Rules* (FFD) and are found in Title 10 Code of Federal Regulations, Section 26, or ubiquitously known in the industry as 10 CFR 26. The initial Fitness-for-Duty rule was published in 1989. This rule requires that each nuclear power plant licensee establish a Fitness-for-Duty program. The NRC crafted these rules at the same time that the HHS Mandatory Guidelines were put together. The NRC adopted the fundamental requirement of using MROs, certified laboratories, and many of the procedural safeguards.

There were, however, a few fundamental differences in philosophy and goals between the HHS Mandatory Guidelines and the NRC fitness-for-duty programs. The NRC had an interest in deterrence of illegal drugs, but the NRC and the industry as a whole also was deeply interested in the concept of overall “fitness” of the employee, the safety of operations, the overall security of the facility and “trustworthiness” of individuals who had access to nuclear plants and facilities. As a result of these considerations, the NRC program that was adopted back in 1988 looked similar to the HHS procedures but contained a number of radically different elements.

First, the NRC gave the individual nuclear electric generating plant (called a licensee) a great deal of flexibility. For example, whereas HHS Mandatory Guidelines restrict drug testing to five categories of drugs, the NRC allows the licensee to test for additional drugs and to test for drugs at lower cutoff levels than specified and required in the HHS Mandatory Guidelines. The NRC also allowed for the on-site testing for specimen validity at the collection site, and allowed the licensee to have an on-site immunoassay screening laboratory for initial screening of urine specimens. The NRC also adopted a modified stand-down provision that a licensee can use. All these deviations from HHS provisions were controversial at the time, but they have worked for the nuclear power industry.

Another fundamental difference is that unlike the DOT/HHS testing model, the NRC does not require the MRO to receive all of the laboratory results from the certified laboratory, or even to review the negative results. (Everything in the nuclear industry is reviewed about ten times — but not by the MRO.) The results typically go to a fitness-for-duty coordinator, who again typically has access to all the testing information, including the MRO records. This is a very different process than seen in DOT testing. On the other hand, the MRO in the nuclear industry often has to play an expanded role in respect to management of the health, qualifications, and prescription drug use of the employees in the program.

In 1995, the NRC published a proposed update to its Fitness-for-Duty Regulations. These proposed rules were open for comment in 1996, were debated, and then went into a state of

regulatory limbo. Meanwhile, utilities continued to follow the existing rules and modify and update their programs within the regulatory framework of 10 CFR 26. While the proposed rules were in limbo, a lot happened in other areas of testing. HHS implemented program documents giving laboratories guidelines on how to test for adulterants, and subsequently adopted a mandatory specimen validity rule. DOT has rewritten its drug and alcohol testing rules, adopted procedures for managing insufficient urine volume (shy bladder), and established procedures for testing of adulterated and substituted urine. During this time the nuclear industry was going through a challenging period of reorganization in order to adapt to a new “deregulated” industry of gyrating market conditions.

In 2000, prior to establishing an implementation date for the 1995 “new” rule to go into effect, the NRC held a meeting for the industry to provide any additional clarifications. It was a difficult meeting for all parties. What became clear was that many aspects of what were viewed as enhancements in 1995 looked stale in 2000. In 1995, the regulatory language was still of the old school, as opposed to the new question-and-answer format used by DOT and HHS.

The world changed in September 2001, and the NRC refocused its efforts on counterterrorism and security. In the fitness-for-duty area there was more emphasis and interest in managing fatigue and enhancing background checks. The NRC staff was continuing to work on updating the fitness-for-duty rules, and the industry recognized the benefit of incorporating the DOT and HHS experience with respect to managing specimen validity. The NRC and the nuclear industry also took the opportunity to develop a comprehensive rule (framed as amendments to the existing rules) that better addresses the issues of adulteration, emerging technologies, drug and alcohol abuse, and safety in a less cumbersome way and to integrate a decade and a half of experience from well-run programs.

Thus, after a 10-year period of struggle and at times a mind-numbing regulatory process, the NRC pre-released a proposed new rule in April 2005. This new proposal represents countless hours of work on the part of all of the stakeholders, and a significant catch-up and enhancement of the existing program. True to its original intent, the “fitness-for-duty” rules include the procedures and requirements for the management of “fatigue,” which are outlined below.

10.2.3.2 The 2005 Proposed Amendments to the NRC Fitness-for-Duty Rules

On May 16, 2005, the NRC published in the *Federal Register* a notice that stated that it intended to propose:

A rule (that) would amend the Commission’s regulations to ensure compatibility with the Department of Health and Human Services guidelines, eliminate or modify unnecessary requirements in some areas, clarify the Commission’s original intent of the rule, and improve overall program effectiveness and efficiency and establish threshold for the control of working hours at nuclear power plants to ensure that working hours in excess of the thresholds are controlled through a risk-informed deviation process. Because of the issues raised in response to the earlier affirmed (fitness for duty) rule, a new proposed rule will be published, including provisions to provide significantly greater assurance that worker fatigue does not adversely affect the operational safety of nuclear power plants. This new proposed rule is scheduled to be provided to the Commission by June 1, 2005.*

This new fitness-for-duty rule is available on the NRC Web site.† It is awaiting approval from the Office of Management and Budget, which should take some additional time. The rule when published will provide at least 120 days before going into effect.

As could be anticipated in updating a 10-year-old drug and alcohol testing rule, the proposed fitness-for-duty rule contains a significant number of changes to the existing program. The following

* The NRC is reviewing the public comments and projects that the rule will become final in January 2007.

† Go to nrc.gov and use the search feature to find “fitness for duty.” The searcher should find the old rule, the history of the rule, a wealth of background material, and the new rule in its pre-published form.

are some of the most significant changes that deal directly with drug and alcohol testing. The proposed new *fitness-for-duty* rule would:

- Add requirements for validity tests on urine specimens to determine if a specimen has been adulterated, diluted, or substituted. At the request of stakeholders, the rule would permit licensee testing facilities to perform validity screening tests using non-instrumented testing devices, as proposed by HHS on April 13, 2004 (69 FR 19672), but not yet incorporated into final HHS guidelines.
- Add a requirement that assays used for testing for drugs in addition to those specified in this part, or testing at more stringent cutoff levels than those specified in this part, would be evaluated and certified by an independent forensic toxicologist. (§26.31(d))
- Add a requirement that cutoff levels would be applied equally to all individuals subject to testing. (§26.31(d))
- Establish a process for determining whether there is a medical reason that a donor is unable to provide a urine specimen of at least 30 ml. (§25.119)

Alcohol Testing

With respect to alcohol testing the new provisions would:

- Add requirements for the use of oral fluids (i.e., saliva) as acceptable specimens for initial alcohol tests.
- Lower the blood alcohol concentration (BAC) at which a confirmatory test is required from 0.04 to 0.02%. (§26.31(d)) This is a significant change. One of the reasons for the change has been the observation of the occasional donors who had been on the job for a few hours and still had a breath alcohol test above 0.03%.
- Eliminate blood testing for alcohol. (§26.31(d)) Blood testing is allowed under the existing program as a “voluntary procedure” for individuals who had tested positive on two sequential evidentiary breath testing devices. This extraordinary provision allowing a positive donor to obtain a blood alcohol result was incorporated in an abundance of caution and concern over defending the results in respect to an individual’s challenge of the EBT alcohol testing results. The elimination of this provision is recognition that having not just one but two evidential breath testing devices is overkill.

Sanctions

As distinguishable from the general DOT rules (with a few notable exceptions in the FAA rules), the NRC does specify employment sanctions for violations of the fitness-for-duty rule. The sanctions are made more severe under the new provisions. Significantly, they include:

- Require unfavorable termination of authorization for 14 days for a first confirmed positive drug or alcohol test result. (§26.75(e))
- Increase the authorization denial period for a second confirmed positive drug or alcohol test result from 3 to 5 years. (§26.75(e))
- Add permanent denial of authorization for additional FFD violations following any previous denial for 5 years. (§26.75(g))
- Require permanent denial of authorization for refusing to be tested or attempting to subvert the testing process. (§26.75(b))
- Add a 5-year denial of authorization for resignation to avoid removal for an FFD violation. (§26.75(d))

Catch-Up Provisions

The new rule also proposes a number of “catch-up” provisions that incorporate standards already established in DOT and HHS rules. These provisions include such items as:

- Add cutoff levels for initial validity tests of urine specimens at licensee testing facilities and certified laboratories, and require tests for creatinine, pH, and one or more oxidizing adulterants. The rule would not allow licensees and other entities to establish more stringent cutoff levels for validity testing, and would also specify the criteria for determining that a specimen must be forwarded to an HHS-certified laboratory for further testing. (§26.131)
- Replace and amend cutoff levels for initial tests for drugs and drug metabolites to be consistent with HHS cutoff levels. (Decrease the cutoff level for marijuana metabolites from 100 to 50 ng/ml. Increase the cutoff level for opiate metabolites from 300 to 2,000 ng/ml.) (§26.133)

Provisions for MROs

With respect to MROs, the following provisions are being proposed:

- Clarify requirements concerning donor requests to test the specimen in Bottle B of a split sample. (§26.135)
- Clarify and expand the requirements relating to qualifications, relationships, and responsibilities of the MRO.
- Add a requirement that the MRO pass a certification examination within 2 years of rule implementation. (§26.183)
- Add specific prohibitions concerning conflicts of interest. (§26.183)
- Specify MRO programmatic responsibilities. (§26.183)
- Establish the requirements and responsibilities of the MRO staff.
- Add a requirement for the MRO to be directly responsible for the activities of individuals who perform MRO staff duties. (§26.183)
- Add a requirement that MRO staff duties must be independent from any other activity or interest of the licensee or other entity. (§26.183)
- Prohibit the MRO from delegating his or her responsibilities for directing MRO staff activities to any individual or entity other than another MRO. (§26.183)
- Specify the job duties that MRO staff may and may not perform. (§26.183)
- Clarify and expand MRO responsibilities for verifying an FFD violation.
- Make the MRO responsible for assisting the licensee or other entity in determining whether the donor has attempted to subvert the testing process. (§26.185)
- Provide detailed guidance on circumstances in which the MRO may verify a non-negative test result as an FFD policy violation without prior discussion with the donor. (§26.185)
- Clarify MRO responsibilities when the HHS-certified laboratory reports that a specimen is invalid. (§26.185)
- Specify actions the MRO may take if he or she has reason to believe that the donor may have diluted a specimen in a subversion attempt, including confirmatory testing of the specimen at the assay's lowest level of detection for any drugs or drug metabolites. (§26.185)
- Add requirements for the MRO to determine whether a donor has provided an acceptable medical explanation for a specimen that the HHS-certified laboratory reported as adulterated or substituted. (§26.185)
- Incorporate HHS recommendations on verifying a positive drug test for opiates. (§26.185)
- Incorporate federal policy prohibiting acceptance of an assertion of consumption of a hemp food product or coca leaf tea as a legitimate medical explanation for a prohibited substance or metabolite in a specimen. (§26.185)
- Provide detailed requirements for evaluation of whether return-to-duty drug test results indicate subsequent drug use. (§26.185)

Return to Duty

In respect to return-to-duty provisions the new proposed rule would:

- Add a new position, substance abuse expert (SAE), to the minimum requirements for FFD programs and specify the qualifications and responsibilities of the SAE. (§26.187) This SAE may or may

not be defined as the SAP is defined in DOT regulations. Nevertheless, the change in the acronym is a significant improvement.

- Specify the role of the SAE in making determinations of fitness and the return-to-duty process, including the initial evaluation, referrals for education and/or treatment, the follow-up evaluation, continuing treatment recommendations, and the follow-up testing plan. The rule would specify the role of the SAE in determinations of fitness based on the types of professional qualifications possessed by the SAE. (§26.189)

Managing Fatigue

The new rule integrates fatigue management and fitness for duty. It is a logical association, but the development of sound fatigue rules that are not burdensome on the industry is a daunting challenge. In summary, the proposed rules:

- Establish program requirements for fatigue management at nuclear power plants.
- Codify a process for workers to self-declare that they are not fit for duty because of fatigue. (§26.197)
- Require training for workers and supervisors on symptoms of and contributors to fatigue and on fatigue countermeasures. (§26.197)
- Require licensees to include fatigue management information in the annual FFD program performance report that would be required under §26.217, including the number of waivers of the individual limits and break requirements that were granted, the collective work hours of any job duty group that exceeded the group average limit in any averaging period, and certain details of fatigue assessments conducted. (§26.197)

10.2.3.3 Conclusion

This is just an outline of the significant differences. Overall, the NRC has had an exceptional record of performance, even while working with a rule that was clearly long in the tooth. A key to the success of the NRC fitness-for-duty program has been a combination of the rigorous analysis that nuclear managers bring to the table in respect to safety concerns as well as some degree of regulatory flexibility.

One can also anticipate that there may be some changes between the pre-published amendments and what becomes final law, and no doubt the NRC will be evaluating the final rule that HHS is expected to publish with respect to the effectiveness of alternative drug testing technologies. It is also safe to assume that it will be unlikely that the NRC will fall behind again in the race for effective management of substance abuse and employee fitness.

10.3 WORKPLACE DRUG TESTING OUTSIDE THE U.S.

Anya Pierce, M.Sc., M.B.A.

Toxicology Department, Beaumont Hospital, Dublin, Ireland, U.K.

10.3.1 Introduction

Although workplace drug testing (WDT) began in the U.S., it is increasingly prevalent in all parts of the globe.¹ A major contributor to its spread was U.S. multinational corporations introducing the practice internationally. The amount of WDT performed is still minimal compared to the U.S. but it is steadily increasing.

WDT began in the U.S. military and this trend has continued worldwide, with armed forces everywhere adopting the practice. It is impossible to obtain accurate statistics for most countries, and even when statistics are available, there often is no agreement about what constitutes WDT. For example, many countries include prison testing programs in their statistics.

There is an aura of secrecy about WDT in Europe, as if it were somehow shameful for companies to admit involvement. This is hard to understand because WDT in Europe and Australia is led by health and safety concerns. The greater prevalence of trade unions in Europe appears to inhibit the acceptance of WDT. There is also much greater use of point-of-care testing (POCT) outside the U.S., with its consequent problems of little or no elements of quality assurance.

10.3.2 Scope

This section covers the state of workplace drug testing and the development of regulations, both in place or proposed, accepted methods, and cutoffs in Europe, Australia, and other international arenas.

10.3.3 Workplace Drug Testing in Europe

10.3.3.1 History

In 1989, Spain held the presidency of the European Economic Community (EEC) and made the following proposals concerning drug testing:

- Examine the criteria currently used for reporting positive results, including the need to distinguish between screening and confirmation results.
- Examine the existing quality assurance programs.
- Examine the validity of certified reference materials for illicit drugs and their metabolites.

This work was followed by a questionnaire to collect information on:

- Substances tested
- Cutoff values
- Test methods
- Need for duplicate samples
- Interpretation and transmission of results
- External quality assurance practices

Last, a survey on quality and reliability was distributed. This led to the formation of an expert group under the aegis of Marie Therese Van der Venne of DG VI of the European Commission. Several meetings were held in Luxembourg with one or two representatives from each EEC country. This culminated in a 2-day meeting in Barcelona with original representatives and additional experts. Recommendations² were finalized and published in journals nominated by the experts from each country under the following categories:

- Sample handling and chain of custody
- Cutoff values
- Analytical methodology
- Educational requirements
- External quality assurance and accreditation

These recommendations met with a great deal of opposition. Some thought they were too limited, while others thought they were too restrictive. Some disliked the specific cutoffs selected. Different countries had widely varying attitudes, socially and legally, to drug use.

10.3.3.2 European Workplace Drug Testing Society

The sponsor in the European Commission died suddenly and workplace testing guidelines failed to progress until a meeting entitled “Drug Testing at the Workplace” was held in Huddinge Hospital in Stockholm, Sweden. This meeting led to the formation of the European Workplace Drug Testing Group (EWDTG) on March 1, 1998. The group consisted of one or two members from each EU country and representatives from Norway and Switzerland. From this core group the European Workplace Drug Testing Society (EWDTS) developed.

The mission of the EWDTS is to ensure that workplace drug testing in Europe is performed to a defined quality standard, in a legally secure manner, and to provide an independent forum for discussion of all aspects of workplace drug testing. Guidelines for urine testing are published and are discussed below. Guidelines for other matrices are under development.

The EWDTS objectives are to:

- Provide the source of expertise on WDT in Europe
- Function as the primary advisor to the European Commission
- Develop relevant literature and dispense information via the EDWTS Web site
- Train medical review officers (MROs)
- Train sample collectors

There is no specific legislation regarding WDT in any country in Europe. Finland had planned to introduce it, but at the last minute deleted the section from the relevant act.

Industries that perform WDT are mainly in:

- Transport
- Information technology
- Petrochemicals
- Shipping
- Pharmaceuticals
- Customer support (call) centers

Testing occurs predominantly at the pre-employment level, although in transport it is also routinely performed after an accident. Government employees outside the U.S. are not tested.

10.3.3.3 Sweden

In 1995, the Swedish government evaluated WDT and found no need for legislation. Instead, it was found preferable for the labor market to regulate this issue itself. In 1998, 23,997 people were tested, of whom 2.3% were positive.

A person working as a cleaner in a non-safety critical area of a nuclear power plant objected to drug testing. The case was referred to the European Court of Human Rights. The court handed down a judgment on March 9, 2004 rejecting the application, saying it was impractical to differentiate employees and that drug testing of all its employees was a proportionate measure that did not violate Article 8.2 of the European Convention on Human Rights. This is the only case law in Europe at present.

10.3.3.4 The Netherlands

Interestingly, the only laws referring to WDT in the EU are in the Netherlands, where pre-employment testing is prohibited. There is also opposition from trade unions and occupational health specialists, who believe that it is an infringement of individual privacy. In companies that do drug testing, it cannot be obligatory and employees have the right to refuse.

Only one laboratory performs WDT. It is located in Rotterdam with a client-base of petrochemical and shipping industries, many of whose employees work offshore. About 20,000 tests are performed annually. Amsterdam, renowned for its coffee shops where small amounts of cannabis can be purchased, has almost no WDT.

10.3.3.5 Spain and Portugal

In a 1994 survey of companies in the Lisbon district with more than 50 workers, Vitòria³ estimated that 20% were doing drug testing. Pinheiro et al.⁴ found that 14% of the largest Portuguese companies (with a workforce greater than 1000) were performing tests in 1997, the majority without correct chain of custody or confirmation.

No statistics are available from Spain. The majority of WDT on the Iberian Peninsula is done by the military. The most representative (and probably sole) indicators of WDT activity are those of the Portuguese army, where positive results have decreased from 17% in 1986 to 5.8% in 1995. Positive cannabis and opiate tests accounted for 4.1 and 1.4% of total positive tests.

10.3.3.6 Luxembourg

Some private companies are performing on-site testing for drugs of abuse, and some companies are sending urine specimens to special laboratories. Again, there are no firm statistics.

10.3.3.7 France

Air France and the automobile industry do the majority of drug testing. Private laboratories provide these services. In August 2004 the Department of Transport allowed occupational physicians in the railroad industry to drug test workers in safety-critical positions.

10.3.3.8 Germany

There is very little WDT in Germany. Most of the major companies in transport and manufacture do not test. Generally, WDT is perceived as an invasion of privacy, although some companies, mainly around Frankfurt, have begun testing.

10.3.3.9 Greece

WDT is done only in Thessaloniki, at the Aristotelian University.⁵ Specimens for analysis come from:

- District attorney offices for testing of prisoners' specimens
- Directorate of Transportation for drivers seeking the reinstatement of driving licenses revoked for previous drug abuse
- Private individuals during pre-employment testing
- Security services under a law passed in 1997
- Prostitutes and housekeepers at houses of prostitution under a law passed in November 1999

10.3.3.10 Ireland

Ireland has a large number of nonindigenous pharmaceutical and information technology companies. The majority of them test at the pre-employment level and use the policies of their parent companies. The armed forces began random testing in September 2002, although they have performed pre-employment testing for many years. Some companies use laboratories in other countries. The use of POCT is widespread; it is estimated that 50,000 tests are performed annually.

In 2006 the Health and Safety Authority enacted into law the Safety, Health and Welfare at Work Act 2005. One of the more controversial sections states as follows:

An employee shall, while at work —

- (a) comply with the relevant statutory provisions, etc.
- (b) ensure that he or she is not under the influence of an intoxicant to the extent that he or she is in such a state as to endanger his or her own safety, health or welfare at work or that of any other person.
- (c) if reasonably required by his or her employer, submit to any appropriate reasonable and proportionate tests, by or under the supervision of a registered medical practitioner who is a competent person, as may be prescribed. This is the first such law in Europe. It still has to be fine tuned to decide which occupations are considered safety critical and what drugs are to be looked for.

10.3.3.11 U.K.

Testing became more prevalent in the 1980s and is growing. The discovery of oil and the opening of oil rigs in the North Sea and chemical and transport industries have increased testing demand. At present, it is estimated that more than 500,000 tests are performed annually. It is not known how many of the analyses are generated from outside the U.K.

The Railway & Transport Safety Act covers air/road/rail and sea, which includes any person in charge of a vehicle and means they can be tested. The rail sector is the most rigorous with pre-employment “with cause” testing for all and random testing for those in safety-critical positions, and education and help for anyone who discloses a problem. Overall, there is a trend of taking a risk assessment approach to drugs and alcohol, and looking at business-critical as well as safety-critical issues.

10.3.3.12 Belgium

The main users of WDT are in transport and the automobile industry. There are again no reliable statistics. The General Medical Council established strict guidelines in 1993: analysis may only be performed in a laboratory, drug testing is only allowed if clinical examination of impairment is not possible, and positive results must be confirmed by another laboratory. A recent (2002) initiative to amend these rules was not successful.

10.3.3.13 Finland

An Act on the Protection of Privacy in Working Life, which was recently enacted into law, covers several aspects of workplace drug testing. The Finnish guidelines on drug testing are the European Workplace Drug Testing (EWDTS) guidelines. WDT in Finland is mostly pre-employment testing, but random testing is increasing. WDT is usually part of health screening and the employer may often be told only that the applicant has failed the medical examination, with no further details provided.

10.3.3.14 Denmark

There is no legislation regarding WDT in Denmark. It is organized at the local level and mainly for the transport sector, offshore workers, and the police force. Persistent findings indicate that up to 12% of the workforce is influenced by one or more drugs.

Approximately 10,000 tests per year are performed, mainly random testing or cluster testing, with very few pre-employment tests. Approximately 90% of all drug tests are performed as on-site testing (immunoassay screening) by health professionals, who also play a role in developing drug-free workplace programs.

10.3.4 Attitude Surveys

10.3.4.1 U.K. CIPD Survey

A 2001 survey of 281 organizations by the Chartered Institute of Personnel and Development reported⁶ that:

- 20% of the organizations were considered safety-critical, 38% partly so
- 56% have an alcohol and drug policy
- 18% carry out drug testing
- 12% perform drug testing when drug use is suspected
- 9% test for pre-employment
- 7% test for post-accident evaluation
- 6% perform random testing
- 6% do post-rehabilitation testing
- 2% test prior to promotion

10.3.4.2 Drug Testing in Prisons

Drug testing in prisons varies within and between countries. Positive tests tend to result in loss of privileges only. A split sample is taken, and re-screening and confirmation are available in some countries upon receipt of payment from the prisoner. The U.K. has a mix of mandatory and voluntary testing. Sweden also tests for anabolic steroids.

10.3.4.3 Employee Attitudes Survey

A survey was conducted in Sweden, Portugal, and Ireland in 2000 to acquire knowledge about attitudes toward drug testing in the workplace.⁷ Questionnaires were given to people who were tested for drugs at pre-employment. The answers were voluntary and anonymous. The questions asked were:

- Do you think that drug testing can be a good method to achieve a more drug free workplace?
- Do you consider donating a urine sample for this purpose in any way offensive?
- If you had a choice, what matrix would you prefer?
- Do you think that narcotics are a problem in our society?
- What are your views on the use of recreational drugs such as cannabis or ecstasy?

The results showed little difference between countries with the Swedish most certain of the benefits of WDT and the Portuguese the least. The Irish preferred urine as a matrix with very few countries in favor of sweat testing. Individuals under 20 and those over 40 saw the least danger in the use of recreational drugs. The main problem with the survey was that the number of participants was small, self-selecting, and the survey should have involved more countries. Interestingly, a number of people who responded had reservations about the failure to differentiate between cannabis and ecstasy use. They felt that ecstasy was much more dangerous and should have been treated separately.

10.3.5 European Laboratory Guidelines for Legally Defensible Workplace Drug Testing

10.3.5.1 Introduction

The EWDTS guidelines⁸ are based on the U.K. WDT guidelines. Urine is the only matrix included at present, although it is planned to introduce breath, oral fluid, hair, etc. The guidelines

Table 10.3.1 European Screening Cutoffs

Drug	ng/ml
Amphetamine	300
Benzodiazepines	200
Cannabis metabolites	50
Cocaine metabolites	300
Opiates (total)	300
Methadone/metabolites	300
Barbiturates	200
Phencyclidine	25
Buprenorphine/metabolites	5
LSD/metabolites	1
Propoxyphene/metabolites	300
Methaqualone	300

represent best practice, which can withstand legal scrutiny, and are intended to provide a common standard throughout Europe. The guidelines have now been accepted by the European Accreditation (EA) body as the benchmark for WDT.

The guidelines include:

- Specimen collection
- Laboratory organization
- Laboratory analysis
- Quality control and quality assurance
- Medical review officer

10.3.5.2 Screening Cutoffs

Table 10.3.1 presents European screening cutoffs.

10.3.5.3 Confirmation Cutoffs

Table 10.3.2 presents European confirmation cutoffs.

10.3.6 U.S.–EU Comparison

Neither the individual European governments nor the EU parliament has shown real interest in WDT compared to the U.S. government. The U.S. has legally enforceable guidelines, while the European guidelines have no legal standing. In Europe, there is greater use of POCT and small non-accredited laboratories. In the U.S., testing is performed in a small number of large laboratories that are accredited and operated under very strict controls. Testing in the U.S. is mandatory for federal employees, which is not the case in Europe.

10.3.7 WDT in Australia and New Zealand

10.3.7.1 Standards

WDT is increasing in Australia. Although mining is the main industry to embrace WDT, other industries are also testing, including:

- Metalliferous
- Quarrying

- Transport
- Construction

Neither transport nor construction industries have introduced a systematic procedure to measure the extent of drug use within their workforce. Some transport industries across Australia do have *ad hoc* testing. Similar to Europe, drug testing in Australia is conducted as part of an overall Occupational Health and Safety policy. Thus, there are many safeguards for employees who test positive. They are not dismissed, but instead are referred to a rehabilitation program. Only after repeatedly testing positive are individuals liable for dismissal.

Many unions and even Employee Assistance Providers do not support drug testing. In general, within the workforce, the most common drugs of abuse identified are cannabis and methamphetamine. The most common drugs detected are therapeutic codeine and pseudoephedrine. Tables 10.3.3 and 10.3.4 present Australia/New Zealand screening and confirmatory cutoffs.

10.3.7.2 The Australian Mining Industry

This industry is the leader in the introduction of drug and alcohol testing of its workforce. Drug testing is carried out as part of occupational health and safety requirements.

The mining industries in Western Australia, Queensland, and New South Wales are in the forefront. Policies, including compulsory drug and alcohol testing, usually require that an employee

Table 10.3.2 European Confirmation Cutoffs

Amphetamine	200
Methylamphetamine	200
MDA	200
MDMA	200
MDEA	200
Other amphetamines	200
Temazepam	100
Oxazepam	100
Desmethyldiazepam	100

LSD/metabolites	1
Propoxyphene/metabolite	300
Methaqualone	300

Table 10.3.3 Australian/New Zealand (AS/NZS 4308) Screening Cutoffs

Drug	ng/ml
Opiates	300
Sympathomimetic amines	300
Cannabis	50
Cocaine	300
Benzodiazepines	200

Table 10.3.4 Australian/New Zealand (AS/NZS 4308) Confirmation Cutoffs

Drug	ng/ml
Morphine, codeine	300
Amphetamine, methamphetamine, MDMA	300
Phentermine, ephedrine, pseudoephedrine	500
Carboxytetrahydrocannabinol	15
Benzoylcegonine, ecognine methyl ester	150
Oxazepam, temazepam, diazepam, nordiazepam, 7-aminoclonazepam, 7-aminonitrazepam, 7-aminoflunitrazepam	150

is not impaired due to the ingestion of illicit drugs. This wording has created problems, as it is impossible to prove impairment, particularly in the case of a positive cannabis test. There is a lobby to increase the cannabis cutoff to reduce this perceived problem. Unfortunately, policy makers have used terminology from established alcohol testing for drug testing. Even though drug testing has been introduced under health and safety regulations, the unions have concerns. They defend an individual's right to privacy, are concerned about the accuracy of drug testing, and state that individuals should not be penalized for using cannabis on their own time.

Each Australian state has its own mining legislation. In effect, it is the duty of mine managers to ensure that no person is impaired by alcohol or drugs while on site. On-site drug testing is well established. Accredited laboratories perform confirmation analyses. Although there are no legal requirements, most companies select laboratories that are accredited by the National Association of Testing Authorities (NATA) to conduct analyses according to Australian/New Zealand Standards AS/NZS 4308.

More recently, drug and alcohol testing has been extended to include contractors to the mining industry. To date, contractors present a greater risk for impairment than do employees of a company. In due course, it is expected that testing will significantly reduce the incidence of recreational drugs by workers, either employed full time or contracted to the mining industry.

10.3.7.3 New Zealand

Laboratories perform WDT work to the standards of the AS/NZS 4308.⁹ The 2001 standard is currently being updated to include a section for use of "on-site" screening devices. Standards Australia is also developing an Oral Fluid Standard.

The number of tests is rising each year. In 1998/1999, about 3000 urine specimens were tested. This rose to an estimated 50,000 in 2005/2006.

The industries that test are divided as follows (2005/2006):

Road/Horizontal Construction	21%
Forestry	15%
Transport	13%
Meat/Poultry	11%
Dairy	10%
Fishing/Shipping	6%
Aluminum Smelting	4%
Power/Oil	3%
Manufacturing	2%
Vertical Construction	2%
Mining	<2%
Personnel Consulting	<2%

The majority of testing (78%) is at pre-employment, followed by random (15%). Only 2% of the tests are performed after an accident/incident or for "just cause."

Percentage positives in 2005/2006 were 8% (pre-employment), 13% (random testing), and 30% (post-accident or just cause).

10.3.8 WDT in South America

10.3.8.1 Introduction

Workplace drug testing is not a common practice in South America. Most countries do not have established guidelines or policies. Generally, it is performed because the company (usually North American based) requires it as part of a global policy of WDT. The most notable case is Exxon, which requires all of its employees to undergo testing. The tests are mainly performed in a U.S. laboratory and conform to SAMHSA/NIDA guidelines.

10.3.8.2 Brazil

WDT began in 1992 with oil companies and has broadened to include transport and car manufacture, as well as the state police. Since 1992, more than 40,000 tests have been performed and they conform to SAMSHA/NIDA requirements. Over 80% of these tests have been done in the past 3 years. Tests are mainly in urine, but can include hair and oral fluid. Positive tests are handled according to the individual company's drug prevention program. This may include outright dismissal, but the vast majority of companies adopt a more tolerant approach with rehabilitation and treatment. An individual is usually allowed up to three positive drug tests prior to dismissal.

This latter approach has yielded positive results, with many employees voluntarily seeking help for their drug/alcohol problems. When employees perceive that they will receive adequate and sympathetic treatment, rather than dismissal, they are more prone to accept rehabilitation.

The rate of companies adopting a drug prevention policy with testing is increasing at the rate of 5 to 7% a year. Government policy is neither for nor against WDT. It is seen as one important step in the antidrug campaign: it promotes issues of occupational health and safety.

10.3.8.3 Other South American Countries

Argentina: There is no national program and only one company (Exxon) requires it.

Bolivia: There is no official drug-testing program apart from companies that require testing as part of a global program.

Chile: It is starting to develop policies but without any testing so far.

Colombia: Again only one oil company (Exxon) has a WDT program.

Paraguay: A WDT program is beginning, but the tests will be performed in Brazil.

Venezuela: Some major oil companies have WDT programs with testing performed abroad. According to Dr. Lilia Scott (M.D.), there is great difficulty in implementing such programs in the country, as the government does not endorse WDT.

Ecuador, Peru, Uruguay, Guyanas (Guyana, Suriname, and French Guyana). There are no reports of WDT in these countries.

10.3.9 Conclusion

WDT is minimally performed around the world compared to in the U.S. It is not envisaged that it ever will become as prevalent. In the U.S., there are rigid regulations for all aspects of drug testing from collection to reporting. The rest of the world does not have the same safeguards. There is much more use of POCT with all the attendant problems of correct use of the device. Some companies do not inform the employee or presumptive employee that he or she is being tested. Often there is no confirmation test. The use of alternative matrices for WDT is also increasing.

10.4 ANALYTICAL CONSIDERATIONS AND APPROACHES FOR DRUGS

Daniel S. Isenschmid, Ph.D.¹ and Bruce A. Goldberger, Ph.D.²

¹Toxicology Laboratory, Wayne County Medical Examiner's Office, Detroit, Michigan

²University of Florida College of Medicine, Gainesville, Florida

Although recent national surveys have reported declines in overall drug use, more than 11 million Americans still reported using one or more illicit drug in 1992.¹ In addition, results from several studies targeting specific populations, particularly students in high school and college, show that this downward trend has started to reverse itself.^{2,3} In response to the numerous reports on the incidence of alcohol and drug abuse in the workplace, many employers have introduced substance abuse programs, one component of which is urine drug testing.^{1,4,5} There are several very important differences between this type of testing and the laboratory testing performed for medical reasons:

- The test is not performed on a patient; instead, a specimen is collected from a donor.
- The test result is not used to support a diagnosis; it is a single collection that is used in decisions relating to hiring, suspension from employment, referral to employee assistance programs (EAP), and occasionally, dismissal of the employee. Unlike a true clinical test, it has no medical data to support its veracity and, except in rare circumstances, the collection cannot be repeated.
- For regulated industries in which drug testing is required, the laboratory has to be certified by the Department of Health and Human Services.^{6,7} This certification from the Substance Abuse and Mental Health Services Administration (SAMHSA, formerly the National Institute on Drug Abuse) has become the “standard of care” for all drug testing, including that performed for the nonregulated industry. This certification mandates that the laboratory use certain analytical procedures, including gas chromatography mass spectrometry (GC/MS), for confirming immunoassay results, and that it follows rigid chain-of-custody, quality assurance, and data review guidelines.
- The result may be used in a legal environment to support disciplinary action.

Workplace urine drug testing is performed by many laboratories. Because of the strict chain-of-custody and security requirements, most drug testing laboratories are “stand-alone” laboratories, either secured separately from other specialties in larger laboratories or as distinct entities. More recently, there has been a trend toward “mega-laboratories.” These are single locations dedicated to workplace drug testing, processing thousands of specimens per shift. Both service expectations and the economics of drug testing have caused the evolution of such facilities. Today’s expectations are that negative results will be available within 24 h of collection of the specimen, and that positives will be available within another 24 h. Obviously these expectations, together with the desire to decrease costs, will play an increasing part in the choice of the analytical procedures used. Increasing emphasis is being placed on the ease of automation of such procedures.

This chapter outlines the analytical protocols used in such programs. Since there may be significant penalties if a person tests positive for a drug of abuse, it is critical that individuals are not falsely accused of drug use. It is, therefore, important that drug tests are precise and accurate, utilizing validated methodologies. The validity of a drug test is defined as the ability of an assay to detect drug and/or its metabolites in biological fluids following drug administration. This definition encompasses a variety of factors including: assay characteristics such as sensitivity and specificity; and metabolic and pharmacological variables such as dose, route of administration, biological fluid pH, and intersubject variability in absorption, metabolism, and excretion.⁸ Typical urine drug and drug metabolite detection times are given in Table 10.4.1.

10.4.1 Immunoassay Testing

When testing urine specimens for drugs of abuse, laboratories usually screen specimens utilizing a nonspecific immunoassay. These assays may detect classes of drugs, such as the opiates, rather than specific drugs within a class, such as morphine. Since the majority of specimens will test negative, this eliminates the need to do more costly additional testing.

Immunoassays are based on the principle of competition between labeled and unlabeled antigen (drug) for binding sites on a specific antibody. The label may be an enzyme (homogeneous enzyme immunoassays or heterogeneous enzyme-linked immunosorbant assays), a radioisotope (radioimmunoassay), a fluorophore (fluorescence polarization immunoassay), or latex microparticles (particle immunoassay). Immunoassays are characterized by several variables including specificity and sensitivity.

Specificity is the ability of an assay to distinguish the target analyte(s) from other compounds including those with and without structural similarity. Specificity data are typically provided by manufacturers of immunoassays in the form of a package insert. The specificity requirements and design of a particular assay are critical, and may be dependent on the metabolism of the specific drug. For example, since cocaine is rapidly metabolized, all cocaine immunoassays are formulated to detect the primary cocaine metabolite in urine (benzoylecgonine). Furthermore,

Table 10.4.1 Typical Urine Drug and Drug Metabolite Detection Times*

Drug Class	Detection Times ^a
Amphetamines	1–3 days
Barbiturates	Short-acting, 1 day; intermediate- and long-acting, 1–3 weeks
Benzodiazepines	5–7 days
Cannabinoids	1–3 days; greater (several weeks) with chronic use
Cocaine	1–3 days
LSD	Less than 1 day
Methadone	1–3 days
Methaqualone	1–2 weeks
Opiates	1–3 days
Phencyclidine	Up to 3 days
Propoxyphene	1–2 days

^a Detection times vary with method of detection, dose, route of administration, frequency of use, and individual factors.

Table 10.4.2 Immunoassay Cutoff Concentrations (ng/ml)

Drug Group	Target Antigen	Cutoff
Amphetamines	D-amphetamines, D-methamphetamine or both	300 or 1000*
Barbiturates	Secobarbital	200 or 300
Benzodiazepines	Oxazepam or nordiazepam	100, 200, or 300
Cannabinoids	THCA	20, 25, 50*, or 100
Cocaine	Benzoyllecgonine	150 or 300*
Methadone	D-Methadone or D,L-methadone	300
Methaqualone	Methaqualone	300
Opiates	Morphine	300 or 2000*
Phencyclidine	Phencyclidine	25* or 75
Propoxyphene	D-Propoxyphene	300

* Cutoffs used in the SAMHSA Guidelines and the regulated programs.

assays are often designed to be drug class specific (rather than analyte specific) in order that several analytes within a drug class, such as opiates, may be detected with a single assay. Immunoassay performance may be affected by “adulterants,” which may be added to a urine specimen in an effort to subvert the testing process. A discussion on specimen adulteration is presented elsewhere in this volume.

Very early in the evolution of workplace drug testing, it was decided, after considerable debate, that there was a need for assay “cutoffs” to ensure some standardization and equality among the various programs. The “cutoff” is an administrative breakpoint used to distinguish positive and negative specimens. When utilizing assay cutoff concentrations, any specimen that contains drug at a concentration at or above the cutoff will be reported as positive, and any specimen that is less than the cutoff will be reported as negative. Immunoassay screening cutoff concentrations are summarized in Table 10.4.2.

When selecting an immunoassay, there are several factors to consider. These include (1) specificity of the kit to the drug group or drug being tested for, (2) the stability of the immunoassay over time, (3) the ability of the immunoassay either to detect adulterants or to be resistant to them, and (4) the ability of the immunoassay to be automated.

10.4.1.1 Radioimmunoassay

The first laboratory assays developed for the detection of drugs of abuse and their metabolites in urine were based on the radioimmunoassay technique. Heterogeneous radioimmunoassays are

based upon the competitive binding of ^{125}I -radiolabeled antigen and unlabeled antigen for antibody. Analyte antibody and radiolabeled antigen are added to the specimen and the analyte present in the specimen competes with radiolabeled antigen for antibody sites. After precipitation of the antigen–antibody complex with a second antibody reagent, the supernatant is removed and the pellet containing bound antigen is counted using a gamma counter. The amount of radioactivity is inversely related to the concentration of analyte in the specimen.

Radioimmunoassays are very sensitive, generally more so than non-isotopic enzyme immunoassays. Radioimmunoassays have been developed for all common drugs of abuse and have been designed to produce qualitative and semiquantitative results. The disadvantages of radioimmunoassays include limited reagent shelf-life due to the short half-life of ^{125}I , the requirement for additional laboratory safety precautions due to radioisotope use, and considerable technician involvement. They are infrequently used in the urine drug testing industry today, although they are still used for drug testing in alternative matrices, especially blood and hair, as they are less susceptible to matrix effects than many enzyme immunoassays.

10.4.1.2 Enzyme Immunoassay

Enzyme immunoassays for the detection of drugs of abuse in urine initially developed during the early 1970s by Syva Company under the trade name EMITTM (enzyme multiplied immunoassay technique) are now also available from a variety of manufacturers. At the time of its introduction, the EMIT technology offered several advantages over other available procedures for drug testing. The technique provided moderate sensitivity, eliminated a separation stage, utilized reagents with longer shelf-life, could be performed rapidly, and was easily adaptable to manual and automated spectrophotometer-based laboratory instrumentation. The principle of the EMIT assay is based on competition between drug in the specimen and drug labeled with the enzyme glucose-6-phosphate dehydrogenase for antibody binding sites. The enzyme activity decreases following binding to the antibody; therefore, the drug concentration in the specimen can be measured in terms of enzyme activity. In practice, when free analyte is present in the specimen, the displaced free enzyme will convert nicotinamide adenine dinucleotide (NAD) to NADH resulting in a change in absorbance, which is measured spectrophotometrically. The resultant increase in absorbance is proportional to the concentration of the analyte in the specimen.

More recently, this technology has been applied to enzyme-linked immunosorbent assays (ELISA). These assays differ from liquid enzyme immunoassays in that the assays are heterogeneous and are performed on a microtiter plate and are therefore less subject to the matrix effects than are homogeneous enzyme immunoassays. In ELISA diluted specimens and drug-labeled enzyme are incubated in microplate wells coated with fixed amounts of oriented polyclonal antibody. The enzyme (horseradish peroxidase)-drug complex competes for antibodies with the free antigen (drug). After incubation, the wells are washed and a chromogenic substrate (tetramethylbenzidine) is added. Tetramethylbenzidine is converted to a colored product by the unbound drug-enzyme complex. The color reaction is stopped by adding dilute acid. Plates are then read at 450 nm with the intensity of color inversely proportional to the concentration of drug in the sample. These assays offer all of the advantages of radioimmunoassays without radioactive disposal issues and in addition are more amenable to automation using robotic pipettor-diluters, plate washers, and spectrophotometric readers. In addition, as the assay uses an enzyme as a label, shelf-lives are much longer than for radioimmunoassays. Although enzyme-linked immunoassays are not commonly used in very high volume urine drug testing laboratories, they are used in high-volume oral fluid drug testing laboratories and for blood drug testing. Many manufacturers now offer these types of assays.

In the mid-1990s, Microgenics Corporation introduced a new homogeneous assay system for drugs of abuse in urine called cloned enzyme donor immunoassay, or CEDIA[®]. The CEDIA assay is based on the genetically engineered bacterial enzyme β -galactosidase that consists of two inactive fragments. These fragments spontaneously associate to form an active enzyme that cleaves a

substrate, chlorophenol red β -galactopyranoside, producing a color change that is measured spectrophotometrically. In the assay, analyte in the specimen competes with analyte conjugated to one inactive fragment of β -galactosidase for antibody binding site. If analyte is present in the specimen, it will bind to antibody, leaving the inactive enzyme fragments free to form active enzyme. The amount of active enzyme formed and resultant increase in absorbance are proportional to the amount of analyte present in the specimen.

10.4.1.3 Fluorescence Polarization Immunoassay

Fluorescence polarization immunoassays (FPIA) were initially developed by Abbott Laboratories for use by laboratories performing therapeutic drug monitoring and were subsequently adapted for detection of drugs of abuse in urine specimens. The Abbott FPIA system employs a fluorescein-analyte labeled tracer. The tracer, when excited by linearly polarized light, emits fluorescence with a degree of polarization inversely related to its rate of rotation. The analyte of interest, if present in the specimen, competes for a limited number of antibody binding sites with the labeled tracer. If the tracer molecules become bound to its specific antibody, the rotation of the tracer assumes that of the larger antibody molecule, which is significantly less than the unbound tracer molecule, and the subsequent polarization is high. The remaining unbound tracer becomes randomly oriented and rotates rapidly; the subsequent polarization is low. The degree of fluorescence polarization is inversely related to the concentration of analyte in the specimen.

The Abbott FPIA abused drug assays offer laboratories several options that are not available with other systems. All FPIAs utilize a six-point calibration curve, in conjunction with nonlinear regression data manipulation, to estimate unknown specimen drug concentrations. Assay cutoff concentrations can be programmed by the laboratory between the assay sensitivity limit and the highest calibrator concentration. Also, the data printout can be programmed to include either qualitative or semiquantitative results. The assays are amenable to the analysis of other matrices, are very stable, and are resistant to a number of adulterants.

10.4.1.4 Particle Immunoassay

In the early 1990s, Roche Diagnostic Systems introduced the Abuscreen ONLINE® (immunoassay system known as the kinetic interaction of microparticles in solution, or KIMS®). The assay is based on the competition of analyte in a specimen for free antibody with analyte-microparticle conjugate. Particle aggregation occurs in the absence of analyte when free antibody binds to the analyte-microparticle conjugate. The formation of an aggregate scatters light, which results in a reduction of light transmission that can be measured spectrophotometrically. The absorbance change is inversely related to the analyte concentration. The assays can be run on many automated clinical chemistry analyzers, have good stability, and are resistant to a number of adulterants.

10.4.1.5 On-Site Drug Testing

A new market of drug testing devices has grown in recent years due to the desire to decrease turnaround time and cut costs. These “on-site” drug testing kits are typically used at the specimen collection site and are self-contained devices utilizing immunoassay technology for drug testing. The use of these devices has increased in recent years due to their simplicity, ease of performance, and no requirement for expensive equipment or skilled personnel. Minimal operator training is required, results are typically obtained within 10 to 15 min of specimen application, and the presence or absence of a color is the most common method of reading the results. The cost saving occurs in that only those specimens that test positive by this screening assay will be sent to a laboratory for confirmation by an alternative analytical technique. Depending on the specific device and the number of drugs assayed, the cost per test may range between \$3.00 and \$25.00.⁹

The kits may be used in emergency rooms, physician offices, drug treatment centers, probation services, and by employers for pre-employment and random or reasonable cause drug testing to provide preliminary qualitative results. The majority of the devices have built-in validation controls. If the testing is performed for forensic purposes, all positive specimens must be confirmed by an alternative technique. These tests utilize urine as the drug testing matrix and are available to test several drug classes. There are many manufacturers of these devices and their efficacy, as with all assays, depends on their validity in the detection of drugs of abuse. There are several reports of validity assessment studies of these devices.⁹⁻²⁰

10.4.1.6 Testing for HHS-Regulated Drugs by Immunoassay

Amphetamines

Amphetamines are sympathomimetic phenethylamine derivatives with potent central nervous system stimulant activity. Amphetamine and methamphetamine are extensively metabolized and can be detected in urine specimens for up to 3 days. Because methamphetamine is metabolized to amphetamine, amphetamine and methamphetamine-amine are present in urine after methamphetamine ingestion.

In workplace testing, the detection of amphetamines by immunoassay is commonly performed using a kit designed to detect the D-isomers of amphetamine and/or methamphetamine, and not kits designed to detect the amphetamine group. However, there are amphetamine class assays available for clinical toxicology laboratories and others interested in detecting relatively low concentrations of other sympathomimetic amines. Many of these agents, including ephedrine, pseudoephedrine, phentermine, phenylpropanolamine, and phenylephrine, are found in popular nonprescription over-the-counter, cold, allergy, and diet medications. Even though the kits designed to detect the D-isomers of amphetamine and/or methamphetamine have low cross-reactivity to these other sympathomimetic amines, their concentrations in urine may still be high enough to trigger a false-positive test result.

There are important differences between the kits most widely used for amphetamine detection. They all share a 1000 ng/ml cutoff, but some use D-methamphetamine as a calibrator, whereas others use D-amphetamine. When comparing tests for amphetamines, three important questions must be answered: (1) are all assays equivalent in detecting the abuse or use of D-methamphetamine or D-amphetamine, (2) are all assays stereospecific to the D-isomers or will they detect use of L-isomers (Vicks Inhaler) or drugs metabolized to L-isomers (Selegiline), and (3) if the illicit form of methamphetamine used is a racemic mixture, can all assays detect the use? As one might expect, the answers to these questions vary significantly.

The EMIT and CEDIA enzyme assays have good cross-reactivity toward D-amphetamine (the metabolite of D-methamphetamine), and therefore, if the specimen contains 500 ng/ml of D-methamphetamine and 500 D-amphetamine, one would expect the response to be equal to or greater than that of 1000 ng/ml of the calibrator. It should be noted that for the EMIT d.a.u., which uses D-methamphetamine as calibrator, the response would be greater because of the cross-reactivity of D-amphetamine. In fact, one of the claims made about this kit is that 300 ng/ml of D-amphetamine is equivalent to 1000 ng/ml of D-methamphetamine.

A different situation exists with FPIA. Here the calibrator is D-amphetamine and the cross-reactivity toward D-methamphetamine varies, depending on its concentration. In this case there is an increased response toward mixtures of amphetamine and methamphetamine such that combined concentrations of less than 1000 ng/ml may test positive.

A similar situation exists with the KIMS assay, which was specifically designed to satisfy the federal reporting requirement, which states that in order to report a confirmed positive result for methamphetamine in urine (at or above 500 ng/ml), amphetamine must also be present at or above 200 ng/ml.⁷ The assay has little cross-reactivity with pure methamphetamine but enhanced cross-

reactivity when amphetamine is present with methamphetamine. This creates two potential scenarios: (1) the assay may detect specimens that contain less than 1000 ng/ml methamphetamine when amphetamine is present and (2) proficiency specimens containing only methamphetamine that are designed to test the laboratories' ability to follow reporting requirements may not produce a positive test result. For practical purposes using donor specimens, the assay has been found to be equivalent to the EMIT assays in detecting positive specimens from methamphetamine users.²¹

An examination of the cross-reactivities of the different tests toward *l*-methamphetamine might lead one to the conclusion that therapeutic use of Vicks Inhaler would not result in a positive response using these kits. Fitzgerald et al.²² reported concentrations of methamphetamine as high as 6000 ng/ml following use of this decongestant, and these would certainly not be expected to elicit a positive response. He also reported *l*-amphetamine concentrations as high as 455 ng/ml. However, the situation is not as clear as it first seems. The College of American Pathologists, in its Forensic Urine Drug Testing Program, challenged laboratories with a specimen containing approximately 9000 ng/ml of *l*-methamphetamine and 2000 ng/ml of *l*-amphetamine. Greater than 80% of the respondents reported the drugs as positive. Given that the majority, if not all, of the respondents used one of the immunoassays mentioned above, there is likely an additive response in the presence of *l*-methamphetamine and *l*-amphetamine (as there would be for the *D*-isomers). One obvious outcome of this is that the physician reviewing drug test results should routinely request the separation of stereoisomers by GC/MS.

Methamphetamine can be synthesized by different routes and some of these may lead to the formation of *D,L*-methamphetamine rather than *D*-methamphetamine.²³ If the donor has used this racemic mixture, then the urine will be less reactive than if he or she had used the pure *D*-isomer. Under these conditions, 1000 ng/ml of *D,L*-amphetamine may not trigger a positive response using the immunoassays; the exact response will depend on the amount of methamphetamine and amphetamine present and the additive response of the kit to this mixture.

From this discussion, it is apparent that the exact response of a specimen containing various amounts of amphetamines and varying ratios of the stereoisomers cannot be predicted with any certainty and that the various commercially available immunoassays will react differently. Is this important? It is unlikely that any of these kits are failing to detect the majority of methamphetamine abusers; however, the possibility exists that specimens from some abusers are not being detected and that specimens from users of Vicks Inhaler are being reported as positive (particularly outside of the regulated programs). Without a standardization of the various kits used (for example, requiring them to detect 500 ng/ml of *D*-methamphetamine and 500 ng/ml of *D*-amphetamine on a 1:1 basis), the situation will remain as varied as it is today.

Recently there has been significant attention given to the illicit stimulants 3,4-methylenedioxymethamphetamine (MDMA, also known as "Ecstasy") and 3,4-methylenedioxyamphetamine (MDA, also known as the "love pill"). Currently, HHS regulations do not allow for the testing of these drugs. However, some immunoassays designed for testing for amphetamines possess considerable cross-reactivity to these drugs. Immunoassay kits designed specifically to detect these agents are available as well. For example, some ELISA assays (e.g., Immunalysis) have kits specifically designed for the analysis of either *D*-methamphetamine (and MDMA) or *D*-amphetamine (and MDA). Both kits have very low cross-reactivity to the *L*-isomers of methamphetamine and amphetamine, respectively. However, as methamphetamine kit has low cross-reactivity to amphetamine and the amphetamine kit has low cross-reactivity to methamphetamine, these types of kits would not be particularly well suited for drug testing under the HHS Guidelines. A similar situation is encountered for several radioimmunoassays as well.

Cannabinoids

Marijuana is a popular, potent hallucinogen used primarily for its euphoric effects. The psychoactive constituent in marijuana is δ -9-tetrahydrocannabinol (THC). THC is metabolized to 11-

hydroxy- δ -9-tetrahydrocannabinol, which is rapidly metabolized to 11-nor- δ -9-tetrahydrocannabinol-9-carboxylic acid (THCA). THCA may be detected in urine specimens for variable periods of time and potentially for up to several weeks depending on the frequency of use.

Immunoassay techniques are designed to detect cannabinoids in urine specimens utilizing THCA as the target analyte. Other non-cannabinoid analytes usually do not cross-react with the cannabinoid assays. Marinol®, synthetic THC, used for the treatment of anorexia associated with AIDS, will produce positive test results. The original formulation of the EMIT cannabinoid assay was subject to false-positive test results in the presence of ibuprofen. The assay was reformulated in 1986, and is no longer affected by ibuprofen.

Cannabinoid immunoassay cutoff concentrations will affect the percentage of nonconfirmable positive screening results, especially in specimens with urinary concentrations of THCA between 50 and 100 ng/ml. Further, it is difficult to correlate immunoassay response with GC/MS confirmation results for THCA since immunoassay results reflect total cannabinoid metabolite concentration, rather than THCA concentration only.²⁷

A problem associated with the interpretation of urine cannabinoid test results is that positive tests may occur from passive inhalation of marijuana smoke. The presence of cannabinoid metabolites in urine specimens due to passive inhalation is a function of environmental conditions, duration and frequency of exposure, and THC content of the smoked marijuana.²⁵⁻²⁸ Although passive inhalation studies have shown that individuals exposed to marijuana cigarette smoke under typical conditions would not test positive for cannabinoids, in order to avoid interpretive problems, the federally mandated THCA cutoff concentration was initially set at 100 ng/ml. The cutoff concentration was lowered to 50 ng/ml in 1994.⁷ However, passive inhalation studies were performed with marijuana cigarettes containing low concentration of THC (less than 4.0%). Cigarettes seized by law enforcement personnel in recent years have demonstrated THC concentrations exceeding 20%, clearly demonstrating the need to reinvestigate passive inhalation issues.

Cocaine (Metabolite)

Cocaine is a potent central nervous system stimulant and local anesthetic. It is rapidly hydrolyzed to benzoylecgonine and ecgonine methyl ester by metabolic and chemical reactions. Benzoylecgonine, the primary cocaine metabolite in urine, is readily detected for 1 to 3 days. Following chronic use of cocaine, benzoylecgonine may be detected for longer periods of time.

Immunoassay techniques are designed to detect cocaine metabolites in urine specimens utilizing benzoylecgonine as the target analyte. Cross-reactivity with other non-cocaine compounds such as lidocaine, benzocaine, and procaine does not occur and will not produce false-positive test results.

In the mid-1980s it was found that Health Inca Tea, which was sold in U.S. health food stores, contained trace amounts of cocaine. The U.S. Food and Drug Administration has since banned the importation of any tea containing residual cocaine. Yet several studies performed with Health Inca Tea and other teas imported from South American countries clearly show that even very low amounts of cocaine in a beverage can result in a positive urine drug test. Health Inca Tea has been reported to contain an average of 4.8 mg of cocaine/bag²⁹ and between 1.87 and 2.15 mg of cocaine/cup of prepared tea.^{30,31} In four subjects ingesting one cup of Health Inca Tea containing 1.87 mg of cocaine, peak urinary benzoylecgonine concentration ranged from 1400 to 2800 ng/ml 4 to 11 h after ingestion, well above the 300 ng/ml regulated immunoassay cutoff concentration.³¹ In another study where one subject drank a cup of tea containing 2.15 mg of cocaine, the peak urinary benzoylecgonine concentration of 1280 ng/ml occurred 2 h after tea ingestion.³⁰ In a study where 6 oz. of Coca-Cola fortified with 25 mg cocaine HCl was consumed by a 165-lb male, peak urinary concentrations of benzoylecgonine (7940 ng/ml) were obtained at 12 h.³² Urine benzoylecgonine concentrations remained in excess of 300 ng/ml for 48 h.

These studies demonstrate that very small amounts of cocaine, <5.0 mg or about one fifth of a typical intranasal dose (or line), when added to or contained in a beverage, are sufficient to

produce a positive drug test in an unsuspecting subject for cocaine metabolites in urine. In such cases, the detection of unique cocaine metabolites, such as methylecgonidine or ecgonidine, produced after smoking crack cocaine, may prove to be useful in refuting alleged oral ingestion of cocaine after a positive drug test for benzoylecgonine; however, testing for these analytes is not currently permitted under federal drug testing guidelines. Instead, the guidelines provided to Medical Review Officers (MROs) state that unknowing ingestion of cocaine is not an alternative medical explanation for the presence of benzoylecgonine in the donor's urine.

Opiates

Opiates are potent drugs that are routinely utilized as analgesics to treat moderate to severe pain. Legitimate pharmaceutical sources of opiates include morphine and codeine. Heroin, an illicit substance, is most often abused for production of euphoria and avoidance of withdrawal symptoms. Heroin is rapidly metabolized to 6-acetylmorphine, which is further metabolized to morphine. Codeine is also metabolized to morphine. Opiates may be detected in urine specimens for up to 24 h or for several days, depending on the amount and agent administered.

Immunoassay techniques are designed to detect opiates and their metabolites (primarily morphine, codeine, and their glucuronide metabolites) in urine specimens using morphine as the target analyte. Most opiate assays are generally nonspecific and cross-react with many opiate compounds. Under the federal drug testing program, only morphine, codeine, and 6-acetylmorphine may be reported. In nonregulated testing, other opiates, especially hydrocodone, hydromorphone, and oxycodone, are frequently included as part of the opiate panel, although it should be noted that oxycodone frequently has limited cross-reactivity in general opiate immunoassays. Oxycodone-specific immunoassays are available.

Morphine and codeine have been identified in urine specimens of individuals who have ingested poppy seeds and/or poppy seed cakes. Opiate immunoassays are sufficiently sensitive to detect morphine and morphine conjugates in these specimens days following ingestion. These results are true positives, even though not indicative of opiate abuse. Therefore, in the case of a positive opiate test result, additional testing may be required to differentiate the heroin user from the poppy seed consumer.^{25,33} In an attempt to address this issue, in 1997 the mandatory guidelines were changed to increase the initial and confirmatory testing cutoffs for morphine and codeine from 300 to 2000 ng/ml.³⁴ In addition, the requirement for testing for 6-acetylmorphine (cutoff concentration 10 ng/ml) when morphine is present at concentrations at or above 2000 ng/ml was added. These changes were implemented on December 1, 1998.

Phencyclidine

Phencyclidine (commonly known as PCP), a hallucinogen and dissociative anesthetic, is readily detected in urine specimens for up to several days following administration. Immunoassay techniques are designed to detect phencyclidine in urine specimens utilizing phencyclidine as the target analyte. Cross-reactivity with other non-phencyclidine-related compounds is not usually observed except for high concentrations of thioridazine in some assays.³⁵

10.4.1.7 Testing for Other Drugs by Immunoassay

Barbiturates

Barbiturates are central nervous system depressants and are utilized as sedative-hypnotic and anticonvulsant agents. There are many barbiturate derivatives that constitute this class of drugs and are classified as ultrashort-, short-, intermediate-, and long-acting agents. Detection of a specific barbiturate in urine depends upon the type of barbiturate ingested, and ranges from 24 h (short-acting) to several weeks (long-acting).

All immunoassay techniques are designed to detect the majority of short-, intermediate-, and long-acting barbiturates in urine specimens using secobarbital as the target analyte. A positive test result indicates the presence of barbiturates in the urine specimen. Additional testing utilizing a chromatographic technique is necessary to identify the specific barbiturate(s) present.

Benzodiazepines

Benzodiazepines are central nervous system depressants utilized for their anxiolytic, sedative–hypnotic, anticonvulsant, and muscle relaxant properties. There are many benzodiazepines that constitute this class of drugs, and they are classified as ultrashort-, short-, and long-acting agents. Detection of a specific benzodiazepine in urine depends on the type of benzodiazepine ingested and ranges from 5 to 7 days.

Immunoassay techniques are designed to detect benzodiazepine compounds and their metabolites in urine specimens utilizing oxazepam or nordiazepam as the target analyte. A positive test result requires further testing utilizing a chromatographic technique to identify the specific benzodiazepine compound and/or metabolite(s) present in the specimen. Depending on the immunoassay technique, other benzodiazepines, such as alprazolam, clonazepam, lorazepam, and triazolam, may be difficult to detect.

Methadone

Methadone is a synthetic opioid that has analgesic actions and potency similar to morphine. Although its primary use has been in the detoxification and maintenance of heroin addiction, its use is also indicated for treatment of severe pain. This latter use has become much more common in the past few years and reports of methadone abuse and methadone-related fatalities are increasing.³⁶ Methadone is readily detected in urine specimens for up to 72 h after administration.

Immunoassay techniques are designed to detect methadone in urine specimens using methadone as the target analyte. Although the methadone assays usually do not cross-react with compounds structurally unrelated to methadone, the presence of metabolites in urine specimens from individuals administered L-alpha-acetylmethadol (LAAM), a long-acting methadone analogue, may produce positive test results.

Methaqualone

Methaqualone is a central nervous system depressant. Although methaqualone was a popular drug during the 1970s and early 1980s, its use has been replaced by other drugs such as benzodiazepines. Methaqualone is not currently available legally in the U.S. Following administration, methaqualone can be detected in urine specimens for up to 14 days. Immunoassay techniques are designed to detect methaqualone in urine specimens using methaqualone as the target analyte. Cross-reactivity with other non-methaqualone-related compounds is not usually observed.

Propoxyphene

Propoxyphene is a synthetic opioid that has analgesic actions and potency similar to codeine. Its use is indicated for the treatment of moderate to severe pain. Propoxyphene and its primary metabolite, norpropoxyphene, are present in urine specimens for several days. Immunoassay techniques are designed to detect propoxyphene and norpropoxyphene in urine specimens utilizing propoxyphene as the target analyte. Cross-reactivity with other non-propoxyphene-related compounds is not usually observed.

Table 10.4.3 GC/MS Cutoff Concentrations

Drug Group	Common Analyte(s)	Cutoff Concentration (ng/ml)
Amphetamines	Amphetamine, methamphetamine	300 or 500 ^{a,*}
Barbiturates	Amobarbital, butalbital, pentobarbital, phenobarbital, secobarbital	200 or 300
Benzodiazepines	alpha-Hydroxyalprazolam, nordiazepam, oxazepam, temazepam	100, 200, or 300
Cannabinoids	THCA	10 or 15*
Cocaine	Benzoylcegonine	150*
Methadone	Methadone	100 or 300
Methaqualone	Methaqualone	300
Opiates	Codeine, morphine (6-acetylmorphine)	300 or 2000* (10*)
Phencyclidine	Phencyclidine	25* or 75

10.4.2 Confirmatory Testing

Before the introduction of the HHS Guidelines⁶ there was considerable discussion among forensic toxicologists regarding the appropriate analytical procedures to be used to confirm immunoassay results. There was a recognition that these had to be based on a different chemical principle than immunoassay, but there was not a consensus that this needed to be GC/MS. However, the Guidelines mandated that GC/MS be used to confirm presumptive positives from immunoassay testing and its use was further incorporated into the College of American Pathologist's FUDT inspection program. It has now become the standard of practice in workplace drug testing to confirm all initial immunoassay results by GC/MS. Common cutoff concentrations are listed in Table 10.4.3.

Not only was there considerable discussion on the need for GC/MS, there was also considerable debate about the suitability of selected ion monitoring for the identification of drugs and/or their metabolites. Several well-respected forensic toxicologists argued that full scan GC/MS was necessary before a specimen could be reported as positive. Although this argument is still heard today, there is a broad consensus of opinion that selected ion monitoring is an accurate and reliable procedure for identification of these substances. The analytical principles of GC/MS have been well covered by other authors.^{37,38} The HHS Guidelines^{6,7} required certified drug testing laboratories to be inspected every 6 months, and it is this inspection process that has driven the improvement in the confirmation procedures. This section examines some of the quality assurance/quality control procedures that have become common practice in certified drug testing laboratories and briefly discusses some analytical issues.

10.4.2.1 Quality Assurance

To provide adequate control and verification of the analytical process, laboratories must implement appropriate policies and procedures regarding GC/MS analysis. This section is intended to discuss the quality control and quality assurance requirements pertinent to the regulated drug-testing laboratory, although many of the components specified below are directly applicable to any laboratory performing drug testing in biological specimens. Much of the information in this section has been condensed from a comprehensive review of commonly practiced quality control and quality assurance procedures in forensic urine drug testing laboratories.³⁹

Method Validation

Method validation is a process of documenting or proving that an analytical method is acceptable for its intended purpose. For analytical methods to be implemented in laboratory-based regulatory

drug testing programs, the laboratory must be able to demonstrate that the chosen analytical method has the ability to provide *accurate* and *reliable* data. At a minimum, the key assay characteristics to be established and evaluated should include the accuracy, precision, linearity, specificity, sensitivity, carryover potential, and ruggedness of the analytical method. Additional characteristics to be evaluated may include the stability of the analyte under various analytical and storage conditions, identification and concentration of the internal standard(s) for the method, validation of use of partial (diluted) sample volumes, and estimated recovery of the analyte from the matrix.

Accuracy and Precision — Two of the most important assay characteristics to be determined during method validation are accuracy and precision. Together, accuracy and precision determine the error of an analytical measurement. The accuracy of a method refers to the closeness of the measured value to the true value for the sample. Precision, on the other hand, refers to the variability of measurements within a set. It is most often used to demonstrate scatter or dispersion between numeric values in a set of measurements that have been determined under the same analytic parameters.

The accuracy and precision of an assay can be determined by comparing test results utilizing laboratory-prepared standards and controls with those obtained with an established reference method or by analysis of standard reference materials. Secondary checks may involve reanalysis of specimens whose concentrations are already known to be accurate (e.g., patient or proficiency samples analyzed by reference laboratories using a validated method).

Accuracy is generally expressed as the percentage difference from the actual value. The assessment of accuracy must be carried out on mean values that have been calculated from replicate measurements of reference materials containing known concentration of analyte. It has been recommended that accuracy be assessed using a minimum of nine determinations over a minimum of three concentrations (i.e., 3 concentrations/3 replicates each).^{40,41}

Accuracy acceptability ranges in forensic urine drug testing laboratories should not exceed 20% (by convention) of the target concentration. Many laboratories routinely use lower ranges, such as 10%. It should be noted that the acceptable accuracy range selected for initial method validation may differ from that selected for routine use (batch acceptance criteria). For example, a laboratory may require that accuracy be within 10% of the known concentration during method validation, and then choose to increase the acceptable range to 20% for routine daily analysis.⁴²

Precision of an analytical method is usually assessed in two ways: analysis of multiple measurements during a single analytical run (within-run precision) and analysis of single, or mean, measurements over many runs (between-run precision). Precision is expressed as the percentage relative standard deviation or coefficient of variation (CV). Within-run precision can be considered a measure of the precision of an analytical method under optimal conditions. The between-run precision, however, is a better representation of the precision one might observe during routine use of the assay. The precision of an assay should be determined at concentrations below, at, and above the assay cutoff concentration for that assay. This can be accomplished by repeated analyses of quality control samples on a within- and between-batch basis. Precision should be determined not only when validating the methods, but on an ongoing basis. The SAMHSA guidelines currently require annual review of accuracy and precision. Generally, within-run and between-run CV values of less than <15% are considered acceptable.^{43–45} However, greater variability is to be expected as analyte concentrations approach the limit of detection (LOD) of the analytical method and the laboratory might choose to increase the acceptability criterion to 20% at its lowest measured concentrations.⁴⁶

Linearity and Sensitivity of the Analytical Method — The linear range of a method should be established during initial assay characterization and periodically thereafter with specimens containing drug analytes over a wide range of concentrations. In forensic urine drug testing, linearity should be established via evaluation of a plot of instrument response (y) as a function of analyte concentration (x) using least-squares analysis.^{47,48} Using a series of calibrators that have been prepared at various known concentrations of analyte, the individual concentrations of each calibrator

are “reverse calculated” using the regression line generated. Acceptable linearity is demonstrated when the correlation coefficient exceeds a defined value, such as 0.990, and quantitative concentration of each point falls within $\pm 20\%$ of the target value. For purposes of forensic urine drug testing, the limit of quantitation and upper limit of linearity of the assay are typically defined as the lowest and highest concentrations, respectively, where all quantitative *and* qualitative quality control criteria are met. The limit of detection of the assay is the lowest concentration for which qualitative quality control criteria are met. Other approaches (e.g., signal/noise ratios) may be used to establish these parameters and have been reviewed elsewhere.³⁹

The laboratory uses this information to establish the range, or concentration interval, which it will routinely use for analysis of samples. Validating the method over a wider range than that used in daily practice provides increased confidence that the routine standard concentrations are well removed from nonlinear response concentrations.

Specificity of the Analytical Method (Interference Studies) — Specificity refers to the ability of the analytical method to accurately measure an analyte response in the presence of all potential sample components. All methods should at a minimum be investigated for potential interference by endogenous matrix components, as well as common compounds that are structurally similar to the analyte of interest.

The potential interference of endogenous urine components with the assay is most frequently assessed by evaluation of urine specimens from several sources (donors) that are known to be drug-free for the analyte of interest. Assessment of interference from structurally-related compounds can be determined by fortification of urine with high concentrations (e.g., 1 mg/ml) of potentially interfering analytes and cutoff concentrations of target analytes, or with concentrations of analyte that are expected under therapeutic conditions. For example, possible interference with the measurement of amphetamine and methamphetamine may occur due to the presence of sympathomimetic amines such as ephedrine, pseudoephedrine, phenylpropanolamine, and phentermine.⁴⁹ Further, interference with the measurement of morphine and codeine due to the presence of opiate metabolites and synthetic 6-keto-opioids such as dihydrocodeine, hydromorphone, hydrocodone, oxymorphone, and oxycodone has also been described.⁵⁰

The problem of interfering substances may be addressed by employing more selective extraction methods, chromatographic separations, or detection methods. For example, to eliminate potential false-positive amphetamine/methamphetamine results due to the presence of other sympathomimetic amines, aliquots of specimens can be treated with a solution of 0.035 *M* sodium periodate at room temperature, then subjected to extraction. In the presence of periodate, α -hydroxyamines undergo oxidative cleavage removing the potential interferent.⁵¹ It is recommended that periodate oxidation be conducted at pH 7 or lower to prevent possible formation of low levels of amphetamine from extremely high levels of methamphetamine that may be present in the specimen.⁵²

Carryover — The term *carryover* is used to refer to the contamination of a sample by a sample analyzed immediately prior to it.^{53,54} In the urine drug testing laboratory, the term *carryover limit* is used to delineate the concentration of analyte in a sample above which contamination may reasonably be expected to occur. There is at least one common approach to performing such studies that involves the analysis of standards prepared at increasingly higher concentrations of analyte, preferably reflecting the highest concentrations that a laboratory typically encounters during routine analysis of samples. Each standard should be injected separately, followed by injection of a blank or solvent to determine if a signal (response) characteristic of the analyte is present in the sample above a pre-established limit (typically the limit of detection). Once the concentration at which carryover occurs is determined, the laboratory establishes its carryover limit at the next lowest concentration that did *not* have evidence of carryover in the blank or solvent. More precisely, upon completion of carryover studies, a laboratory should define the range of analyte concentrations at which carryover does not occur. The laboratory should also ensure that the quantitative value for

the carryover limit established in the carryover study falls within the linearity of the assay to ensure that the quantitative value is accurate.

It is also advisable to evaluate carryover of an assay on each instrument system, including autosamplers, on which the method is to be performed, although there is no general consensus on this issue. This is to ensure that the established carryover limit is properly applied to data obtained on each system routinely used in the laboratory. It is important that criteria be established for evaluating the acceptability of solvent blanks or negative quality control samples that have been inserted to assess possible carryover.⁵⁵ If carryover is suspected, a potentially contaminated specimen should be reextracted, rather than reinjected, because the extract vial may have been contaminated.

Other Factors — Other factors include selection of a derivatizing reagent, selection of the internal standard(s) for the assay, and selection of ions to monitor for selected-ion monitoring or full-scan analysis. These topics are considered in Section 10.4.2.4 (Analytical Issues).

Another important parameter to assess during the method validation phase is that of stability of the analyte. This includes stability of stock solutions of analyte, as well as stability of the analyte in biological matrix. Stability studies will typically be performed to assess stability under different temperatures (storage conditions) and different lengths of time (in-process stability and long-term stability). It is recommended that the laboratory at least establish analyte stability under its own anticipated storage and processing conditions. While there are many different approaches to the performance of stability studies, a common approach is to use quality control materials prepared at known concentrations to assess stability.⁴³

10.4.2.2 Calibrators and Controls

Assay Calibration

In forensic urine drug testing laboratories, assay calibration is necessary to determine whether an analyte is present in an unknown sample at or above a preestablished administrative cutoff value, as well as to determine the accurate quantitative concentration of the analyte under certain circumstances.⁵⁶ Calibrators are prepared from a mixture of different amounts of known concentrations of analyte standards with a fixed amount of internal standard. The two most common approaches to assay calibration in forensic urine drug testing laboratories are multipoint calibration curves and single-point calibrations.

Multipoint calibration curves must include calibrators that bracket the cutoff concentration. Although many laboratories include a calibrator at the cutoff concentration, it is not required.⁵⁶ For each calibrator, specific ion-abundances are measured for the analyte and internal standard. A ratio is calculated for each calibrator and a calibration curve is generated using a simple least-squares regression model. Generally accepted criteria for acceptable linearity using deuterated internal standards for calibration include a correlation coefficient of at least 0.990, and a y-intercept close to zero, although slightly positive or negative y-intercept values are also acceptable. For assay calibration, the laboratory must also establish whether the regression line will be forced through the origin (a “no-intercept” model) or will not be forced through the origin (an “intercept” model). Selection of a no-intercept model implies that the assay limit of detection is *zero*, which is usually not the case for GC/MS urine drug testing assays. Therefore, in most instances regression through the origin should not be used in assay calibration. Finally, the calculated concentration of all standards against the constructed calibration curve should be within $\pm 20\%$ of their respective target concentrations.

Single-point calibrations utilize a calibrator containing analyte at the assay cutoff concentration. Laboratories then include quality control materials at concentrations below, at, and above and below the cutoff concentration to demonstrate linearity. The quantitative results for the quality control materials used in single-point calibration must fall within 20% of their respective target concentrations.

During assay calibration, the laboratory also establishes acceptance ranges for retention time and ion ratios. Acceptance ranges are established to evaluate each calibrator, control, and unknown specimen in the batch. For single-point calibration assays, the acceptable limits are determined from the calibrator at the cutoff. For multipoint calibration curves, acceptable limits may be determined from either the calibrator at the cutoff *or* from the average of all the calibrators analyzed. The laboratory must apply the acceptable ranges consistently to all calibrators, controls, and specimens in the batch. (See Section 10.4.2.3, Criteria for Designating a Positive Result.)

Chromatographic Performance

The chromatographic performance of an assay should also be assessed before the analysis of specimens. This is achieved readily by the injection of an unextracted performance standard including analyte(s) and internal standard(s). Use of an unextracted standard removes sources of variation due to the extraction procedure and matrix interferences. In addition to permitting evaluation of the quality of the chromatographic system, the analysis of an unextracted standard serves to verify that the analyte(s) of interest elute at the expected retention time, that all MS acquisition windows are appropriately set, and that no unexpected adsorptive system losses have occurred. Evaluation criteria in the standard operating procedure manual should include a thorough description of peak shape, resolution, and signal abundance requirements. A complete review of methods for evaluation of chromatographic performance is beyond the scope of this chapter; however, acceptable alternative criteria for evaluation of chromatographic acceptability can be found in many textbooks and other reference materials.^{54,57–61}

Quality Control

Under the HHS guidelines each assay batch must include a minimum total of 10% open and blind positive and negative quality control samples in an appropriate urine matrix.^{6,7} Quality control samples may be purchased commercially or prepared from a different source or lot of standard material than that used to prepare calibrators. The target concentration at one control must be within approximately 125% of the cutoff concentration; other controls should be prepared at appropriate concentrations in order to regularly access accuracy below and/or above the assay cutoff concentration. It is recommended that a highly concentrated control sample be diluted in a similar manner as diluted specimens during aliquoting in order to verify the accuracy of the dilution technique, if one is routinely used to prepare presumptive positive specimens for confirmation.⁵⁶

To evaluate the efficiency of the hydrolysis process, cannabinoid and opiate control samples containing conjugated THCA and morphine-glucuronide, respectively, should be assayed. Negative urine samples spiked with these reference materials can be prepared, or as an alternative, hydrolysis control samples can be prepared from a combined urine pool of previously confirmed specimens (which would otherwise be discarded). An additional quality control that includes potentially interfering substances (such as a control-containing phenylpropanolamine, ephedrine, phentermine, and/or pseudoephedrine) is also recommended.

Verification of Quality Control Materials — Prior to the use of reference materials to prepare calibrator, control, or internal standard material in the laboratory, the laboratory is required to verify that its chemical identity is correct and that it is of acceptable purity and concentration *independently* from the supplier. At a minimum, most laboratories perform a full-scan GC/MS analysis to verify the chemical identity and purity of the material and compare the obtained spectra with that of available library spectra to determine that significant impurities are not present in the material which might interfere with the method. The isotopic purity of the internal standard can also be verified with this procedure. Additional methods for verification of chemical identity and purity may involve measurement of physical constants, such as melting point or refractive index, as well

as use of other analytical techniques (HPLC, IR, NMR, TLC, or UV/VIS) to detect nonpolar or nonvolatile impurities.⁵⁴ Verification of concentration is most often evaluated indirectly by preparation of calibrators or controls at known concentrations and analysis in routine batches. The laboratory must establish specific evaluation criteria for reference materials, such as spectral match requirements, percent isotopic purity required, and quantitative results. The laboratory must retain documentation of all verification procedures performed.⁵⁶ The laboratory may then use the reference material to prepare calibrators for controls for routine use. Of course, these new calibrators and controls must then be themselves validated for concentration (e.g., $\pm 20\%$ of the target concentration) prior to routine use.

Evaluation of Quality Control Results — In forensic urine drug testing, the most common approach to the evaluation of quality control results is through the use of a fixed-criterion quantitative acceptance range, usually $\pm 20\%$ of the target concentration. The laboratory's standard operating procedure (SOP) manual must thoroughly describe the quality control evaluation criteria to be used and must include a policy for the required course of corrective action if quality control sample results fail to meet acceptance criteria. To assess laboratory performance, all control data, including out-of-limit data, should be recorded in the quality control log in Levey–Jennings or Shewart chart format.^{56,62–67} Out-of-limit data should include documentation of required corrective action. It may be acceptable to reinject a quality control sample one additional time. If the results are still unacceptable, other minimally acceptable protocols include (1) reinjection of calibrators, followed by reprocessing of *all* quality control samples and routine specimen data against the new calibration, *if* the time since the last injection is not excessive and the instrument has not been retuned; (2) reinjection of all calibrators, quality control samples, and routine specimens; and (3) acceptance of negative test results that are less than the LOD and reextraction of all other specimens in the batch.

10.4.2.3 Criteria for Designating a Positive Test Result

Qualitative Criteria

Criteria for designating a positive test result include chromatographic and spectral identification. Chromatographic identification of an analyte requires comparison of the retention time of the specimen with that of a calibrator at the cutoff or the average of multiple calibrators. Generally, the retention time of the analyte should be within $\pm 2\%$ of the retention time as established by the calibrator(s).^{56,68,69}

Further, identification of an analyte requires comparison of ion ratios or full-scan mass spectra, respectively. Acceptable ion ratios for the analyte and its corresponding internal standard are usually calculated using ion abundance data obtained for the cutoff calibrator or by determining the mean ion ratios for all calibrators. It has been demonstrated statistically that while full-scan mass spectrometric provides the maximum confidence for analyte identification, a minimum of three structurally significant ions generated under electron ionization conditions appear to provide adequate information for an identification.^{68,70} If the regulated urine drug testing laboratory uses electron ionization, it is currently required to use a minimum of two ion ratios for identification of the analyte and at least one ion ratio for the internal standard.⁵⁶

The ion ratios for the analyte and its corresponding internal standard obtained for the unknown should not differ by more than $\pm 20\%$ of the target ion ratio and acceptance criteria must be uniformly applied to all specimens within the batch.⁶² The establishment of this 20% acceptance criteria for ion abundance ratios has been determined to be appropriate based on ion statistics.^{68–70} Different ion ratio criteria cannot be applied to different specimens, calibrators, or controls within the batch.

Quantitative Criteria

Regardless of the detection technique, to be designated as positive, the measured concentration of a specimen must be equal to or exceed the established assay cutoff concentration. Quantitative results around the cutoff must be truncated, rather than rounded up to the nearest whole number, so that the statistical bias is toward a “negative” result. Specimens directed for GC/MS retest analyses are not subject to cutoff concentrations and are reported as reconfirmed if the concentration is equal to or greater than the LOD of the method. The specimen retest must also meet all other criteria for designating a positive test result.

If the specimen concentration exceeds the upper limit of linearity for the assay, quantitative reports must state that the concentration of the analyte is “greater than *the established upper limit of linearity*” or be reanalyzed using an appropriate dilution. Also, all criteria for designating a positive test result must be satisfied, including chromatographic performance, ion ratios, and retention time data.

Data Review

All data must be thoroughly reviewed by a minimum of two individuals to verify compliance with the methods specified in the laboratory’s procedure manual and to identify clerical and analytical errors. Batch acceptance criteria include within-range standards and controls and acceptable MS tune, chromatographic performance, ion abundance (adequate signal-to-noise ratio), and ion ratios or mass spectral match quality. Also, the laboratory may choose to monitor the consistency (reproducibility) of the ion abundance for the internal standard to ensure that it has been added appropriately, and at the correct concentration, to each calibrator, control, and unknown in confirmatory analyses. Furthermore, an acceptable calibration curve must be obtained, a lack of carryover must be demonstrated, and chain-of-custody documentation must be in order.

The SOP must also address the handling and reporting of results when duplicate extracts are assayed, or diluted and undiluted extracts are analyzed. Acceptance criteria for duplicates must specify minimum correlation of quantitative results, usually $\pm 20\%$ if both results fall within the assay’s linear range. Both of the results must be equal to or greater than the mandated cutoff concentration. If reporting quantitative results, the least diluted sample within the assay’s linear range is typically reported. Review of specimen data should include comparison of the initial immunoassay response with the GC/MS result, an evaluation of chromatographic performance including presence of interfering or extraneous peaks, retention time, minimum ion abundance, ion ratios or mass spectral match quality, quantitation, extraction efficiency, potential for carryover, and chain-of-custody documentation.

10.4.2.4 Analytical Issues

It is far beyond the scope of this section to discuss specific analytical procedures for confirmation of drugs. Methods are readily available in the literature and have been described for urine as well as other matrices. However, it is important to discuss a few of the specific analytical issues that the laboratory will need to face when performing confirmation testing for drugs of abuse by GC/MS.

Selection of a Derivative

Selection of a suitable derivative is a critical component of an assay when required. There are at least three major reasons for using a derivatized compound. First, the analyte can often be made sufficiently volatile to allow its introduction to the mass spectrometer by gas chromatography, permitting optimal separation of the analyte from possible interfering substances. Second, the

Table 10.4.4 Derivatization Procedures

Drug Group	Drugs Commonly Included	Derivatizing Procedure	Ref.
Amphetamines	Amphetamine Methamphetamine	Acylation Silylation	23, 84–86
Barbiturates	Amobarbital Butobarbital Pentobarbital Phenobarbital Secobarbital	Alkylation	87
Benzodiazepines	Nordiazepam Oxazepam	Silylation	88–90
Cannabinoids	THCA	Acylation/esterification Alkylation Silylation	91–94
Cocaine	Benzoylecgonine	Alkylation Silylation	95, 96
Opiates	Codeine Morphine 6-Acetylmorphine ^a	Alkylation Acylation Silylation	97–100

^a See discussion in text.

stability of the analyte during storage, isolation, and thermal volatilization can be enhanced via formation of the derivatized product. Third, the increase in molecular mass resulting from derivatization on the fragmentation may be beneficial, providing ions which, by virtue of their higher mass, are more specific for the analyte.^{71,72} The ideal derivatization procedure should be convenient and rapid to perform, form a consistent and stable product in high yield, require small volumes, be selective for the analyte of interest, be safe to handle, and should not form by-products that interfere with the analysis.^{73–77}

Table 10.4.4 summarizes the numerous choices of derivatizing reagents available to today's drug testing laboratory. Table 10.4.4 does not include all the analytes that can be included under each drug group. For example, the amphetamines assay can be modified to include MDMA, MDA, and MDE, the benzodiazepines to include α -hydroxyalprazolam, α -hydroxytriazolam, diazepam, and *N*-desalkylflurazepam, and the opiates to include hydrocodone and hydromorphone. Detailed information about these procedures is available in the references listed. However, there are issues associated with a number of the assays that do deserve discussion.

Amphetamines — In the early 1990s, it was discovered that during certain GC/MS procedures, and under certain conditions, methamphetamine can be formed from large concentrations of ephedrine (or pseudoephedrine). Consequently, HHS introduced a requirement that for a specimen to be reported as positive for methamphetamine, it must not only contain at least 500 ng/ml of methamphetamine but also at least 200 ng/ml of amphetamine.⁷ This prevented the reporting of false-positive methamphetamines as there was no evidence of the formation of amphetamine during the GC/MS process. This rule does not apply to nonregulated testing, and there may be noncertified laboratories that have not incorporated the reporting rule into their procedures.

A more reliable procedure for eliminating the potential for false-positive results is to incorporate a pre-oxidation step into the extraction.⁵¹ In this protocol, oxidation with sodium periodate destroys hydroxylated sympathomimetics before the extraction, thereby preventing their conversion to methamphetamine during derivatization or GC/MS. If this procedure is used, then good laboratory practices require the laboratory to analyze a control containing the amphetamines together with high concentrations of the sympathomimetics as part of their standard protocols.

In the initial discussion of immunoassay testing for amphetamines, it was mentioned that under certain conditions L-methamphetamine (together with L-amphetamine) will cause a positive amphetamines response. Because of this, it is important that laboratories incorporate procedures to separate

the stereoisomers into their protocols. Such procedures are based on derivatization with an optically pure derivative of an amino acid.²² Interpretation of these GC/MS results is usually straightforward: specimens from Vick's Inhaler users contain greater than 90% of the L-isomer and those from users of D-methamphetamine contain greater than 90% of the D-isomer.

Benzodiazepines — Over the past 5 years numerous publications have focused on this GC/MS assay for benzodiazepines. Historically, it was possible to convert the parent drugs and their metabolites to benzophenones by acid hydrolysis;⁷⁸ however, this procedure does not allow for the confirmation of α -hydroxyalprazolam or α -hydroxytriazolam, metabolites of two of the newer, and most commonly prescribed, benzodiazepines. Using this procedure it is also not possible to differentiate the use of certain benzodiazepines, leading to potential interpretative difficulties.

For these reasons, acid hydrolysis has fallen out of favor and been replaced with procedures involving GC/MS analysis of the parent drug or their metabolites. Because a number of benzodiazepines and their metabolites are metabolized by glucuronidation, it is necessary to perform a hydrolysis step before extraction. Unlike the hydrolysis used for opiates, which can be either acid or enzymatic, only enzymatic ones can be used in the extraction of the benzodiazepines. Because of the polar nature of the benzodiazepines it is necessary to derivatize them; normally the trimethylsilyl derivatives are formed.

The major issue surrounding benzodiazepine testing is the cutoff to be used for confirmation. Historically, either a 200 or 300 ng/ml cutoff has been used; however, this is inappropriate for many of today's benzodiazepines. For example, to confirm many of the immunoassay positives resulting from alprazolam or flunitrazepam use it is necessary to lower this cutoff to 100 ng/ml. As the potency of these drugs increases it will be necessary to constantly monitor whether the confirmation (and the screening) assays are appropriate for their detection. Even in today's environment it is surprising how many laboratories continue to confirm only nordiazepam and oxazepam.

Opiates — Although morphine and codeine have been confirmed by GC/MS for a number of years, this assay continues to cause laboratories problems. One of the underlying issues is whether to use acid or enzymatic hydrolysis. Although studies have shown that acid hydrolysis is more efficient in releasing the parent drug from its conjugate, it has the disadvantage of resulting in a "dirty" hydrolysate that can cause problems in either solid-phase or liquid-liquid extractions. For this reason (as well as for safety ones) most laboratories use enzymatic methods, and with the correct choice of enzyme and conditions, hydrolysis can occur quickly and efficiently. Finally, acid hydrolysis will destroy 6-acetylmorphine in a specimen whereas enzymatic hydrolysis is more "gentle." However, most laboratories utilize a different analytical procedure altogether when testing for the presence of 6-acetylmorphine as hydrolysis is not required and there are other issues relating to its analysis (see below).

A second issue associated with opiate confirmation is the separation and identification of hydrocodone and hydromorphone in the presence of morphine and codeine. This problem is confounded by norcodeine. One of the most common procedures used involves silylation as the derivatization procedure. When this technique is used, the separation of the trimethylsilyl derivatives of codeine from hydrocodone and those of morphine and hydromorphone can be difficult, particularly when it is required to have greater than 90% resolution. It is true that the derivatives can be clearly identified by choosing the appropriate ions to monitor; however, it is still necessary to use common ions. Under normal conditions, the separation of trimethylsilyl derivatives of morphine and norcodeine is almost impossible to achieve.

Therefore, the confirmation of morphine after codeine use can be impractical if the laboratory uses silylation as a derivatization. Under normal conditions, when the donor has only taken codeine, this may not be important; however, if the donor has taken heroin and codeine a negative report for morphine is extremely misleading. The easiest way to resolve this problem is to use a different derivatizing procedure. Either acylation or acetylation is suitable; however, acyl derivatives are

notoriously unstable. Acetylation with acetic anhydride or propionic anhydride is recommended. Although it is more time-consuming from an extraction point of view, the derivatives are well separated chromatographically.

For the analysis of 6-acetylmorphine, silylation is the method of choice although other methods have been used. It is obviously inappropriate to use acetylation as this will acetylate both 6-acetylmorphine and morphine back to heroin, therefore no positive morphine specimens would ever be negative for 6-acetylmorphine! As the regulated laboratory is required to detect 6-acetylmorphine at a cutoff concentration of 10 ng/ml compared with 2000 ng/ml for morphine and codeine, linearity considerations make simultaneous analysis for the determination of morphine, codeine, and 6-acetylmorphine impractical.

Selection of an Internal Standard

The selection of a suitable internal standard is highly linked to the appropriate selection of a derivative (if needed) for the assay as well the particular ions to be monitored for analyte identification and quantitation. An ideal internal standard behaves identically to the analyte throughout the extraction, chromatographic separation, and ionization processes. Deuterium-labeled analogues are the most frequently used stable isotope internal standards in urine drug testing laboratories. Several factors are important to consider when selecting the deuterium isotope-labeled internal standard to be used in an assay. The isotope should not undergo exchange under any of the conditions under which it will be used, such as the extraction, derivatization, or chromatographic separation procedures, as well as the mass spectrometer source.⁷⁹

In addition, the isotope must be stable under routine storage conditions, so that exchange of deuterium and hydrogen does not occur.⁸⁰ The isotopic variant selected should have a molecular weight three or more mass units greater than the unlabeled compound because the naturally occurring heavy isotope content of organic compounds in general produces ions of significant intensity at one or two mass units above each carbon-containing compound in the analyte's mass spectrum.^{79,81–83} It is therefore critical that the isotopic variant is of high purity (>99%) to prevent interference with the analyte of interest during the analysis. Also, the labeling of the isotope should be in such a manner that it is located in the molecular structure so that, after the fragmentation or ionization process, a sufficient number and intensity of high-mass ions that retain the label are present and will not interfere with the intensity measurement of the corresponding ions derived from the analyte.⁸³ The laboratory must carefully evaluate the concentration of internal standard used in its assay to ensure that there is no contribution to analyte signal itself. Generally, ions of high, even mass-to-charge ratios have fewer possible origins and are therefore more likely to be characteristic of a particular analyte. It is recommended that laboratories using selected-ion monitoring utilize at least three characteristic ions for the analyte of interest, and a minimum of two characteristic ions for the internal standard.⁵⁶

Selection of Ions

There has been considerable discussion regarding the choice of ions to monitor and whether they are suitable for identification purposes. For most analytes of interest this is not a problem; however, for some it is. Analytes that clearly fall into the first category include benzoylecgonine, the opiates, and THCA.

Amphetamines — Unless amphetamine and methamphetamine are derivatized, their base peaks in the electron impact mode are 58 and 44 m/z, respectively. These two masses are certainly not diagnostic as they represent a dimethylamine and a methylamine fragment, respectively. Second, monitoring such low ions can lead to a loss of chromatographic selectivity because of the potential

for co-extracted interfering compounds with low mass ions. Derivatization with a perfluoroacyl reagent (e.g., heptafluorobutyric anhydride, HFBAI) will result in ions of considerably higher mass and generally much “cleaner” ion chromatograms. However, there is still need for caution in the GC/MS confirmation of amphetamines because of the potential for interferences from other sympathomimetics as was previously discussed.

Barbiturates — The barbiturates (amobarbital, butabarbital, butalbital, pentobarbital, phenobarbital, and secobarbital) are frequently included in nonregulated drug testing programs. Their confirmation presents some difficulty because of the similarity of electron impact mass spectra of certain barbiturates and the absence of a clearly defined third ion for the analyte. For example, the mass spectra of amobarbital, butabarbital, and pentobarbital include two major ions, at 141 and 156 m/z. A similar situation exists with butalbital and secobarbital (167 and 168 m/z). In addition these five barbiturates elute closely together on the majority of capillary columns used today. Phenobarbital has two distinctly different ions (and is well separated chromatographically) at 204 and 232 m/z. Therefore, laboratories performing this confirmation without a derivatization step are, in essence, basing their identification of the barbiturates more on retention time than on the ions monitored. One solution to this problem is to derivatize the barbiturates before GC/MS. This results in more diagnostic ions and improves the chromatographic separation. In our laboratory, alkyl derivatives are formed using Meth Elute.

Benzodiazepines — As previously discussed, GC/MS confirmation of this group of drugs is difficult; however, one of the issues with developing a procedure for these drugs is the choice of ions to monitor. All of the benzodiazepines contain a halogen (fluorine, chlorine, or bromine). If the choice is to monitor a fragment containing chlorine or bromine, the laboratory should be careful not to choose a second fragment that is simply one containing a chlorine or bromine isotope.

Methadone and Propoxyphene — Assays for these two drugs are based on confirming the presence of the parent drug, and are faced with the same problems as those designed to confirm the presence of underivatized amphetamine and methamphetamine: the base peak in the electron impact mass spectra represents an alkyl amine moiety. It is therefore necessary to choose ions of low intensity for monitoring purposes, or to establish assays based on the metabolites (EDDP for methadone and norpropoxyphene for propoxyphene).

Phencyclidine — Most confirmation assays for this drug monitor the following ions: 200, 242, and 243 m/z. Obviously 243 m/z is simply the carbon isotope fragment corresponding to the 242 m/z ion. However, in this case there are no other suitable diagnostic ions. Fortunately, the 243 ion arises from a different molecular fragment and does not arise solely as result an isotope of the 243 ion.

10.5 ANALYTICAL APPROACHES FOR DRUGS IN BIOLOGICAL MATRICES OTHER THAN URINE

Pascal Kintz, Pharm.D., Ph.D., Marion Villain, M.S., and Vincent Cirimele, Ph.D.

ChemTox Laboratory, Illkirch, France

It is generally accepted that chemical testing of biological fluids is the only objective means of diagnosis of drug use. The presence of a drug analyte in a biological specimen can be used as evidence of exposure. The standard procedure in drug testing is the immunoassay screening, followed by the gas chromatographic/mass spectrometric (GC/MS) confirmation conducted on a urine sample.^{1,2} More recently, a variety of body specimens other than urine, such as oral fluid, sweat, or hair, have been proposed to document drug exposure. It appears that the value of alternative specimen analysis for the identification of drug users is steadily gaining recognition. This can be seen from its growing use in pre-employment screening, in forensic sciences, and in clinical applications.³⁻⁵

The advantage of these samples over traditional media like urine and blood is that collection is almost non-invasive, relatively easy to perform, and may be achieved under close supervision to prevent adulteration or substitution of the sample. Tools for the detection of drugs in alternative specimens utilize traditional technology, although some limitations are imposed that require special attention:

1. The specimen volume or mass is often small.
2. The target analytes are different from urine.
3. The analyte concentration is lower than in urine.
4. The sample preparation for drug analysis can be more difficult.

Although remarkable advances in sensitive analytical techniques enable drug confirmation in oral fluid, sweat and hair today,⁶ limited progress has been made in the development of commercial collection devices, on-site and laboratory-based commercial screening assays, quality control materials, proficiency-testing programs, and regulatory guidelines for utilization of alternative matrices in drug testing.

10.5.1 Hair

In the 1960s and 1970s, hair analysis was used to evaluate exposure to toxic heavy metals, such as arsenic, lead, or mercury. This was achieved using atomic absorption spectroscopy that allowed

detection in the nanogram range. At that time, examination of hair for organic substances, especially drugs, was not possible because analytical methods were not sensitive enough. Examination by means of drugs marked with radioactive isotopes, however, established that these substances can move from blood to hair and are deposited there. Ten years after these first investigations, it was possible to demonstrate the presence of various organic drugs in hair by means of radioimmunoassay (RIA). In 1979, Baumgartner and colleagues¹ published the first report on the detection of morphine in the hair of heroin abusers using RIA. They found that differences in the concentration of morphine along the hair shaft correlated with the time of drug use. Today, GC/MS is the method of choice for hair analysis and this technology is routinely used to document repetitive drug exposure in forensic science, traffic medicine, occupational medicine, clinical toxicology, and more recently in sports.

The major practical advantage of hair testing compared to urine or blood testing for drugs is that it has a larger surveillance window (weeks to months, depending on the length of the hair shaft, against 2 to 4 days for most drugs). For practical purposes, the two tests complement each other. Urinalysis and blood analysis provide short-term information of an individual's drug use, whereas long-term histories are accessible through hair analysis. While analysis of urine and blood specimens often cannot distinguish between chronic use and single exposure, hair analysis can offer the distinction.

10.5.1.1 Hair Collection

Collection procedures for hair analysis for drugs have not been standardized. In most published studies, the samples are obtained from random locations on the scalp. Hair is best collected from the area at the back of the head, called the *vertex posterior*. Compared with other areas of the head, this area has less variability in the hair growth rate, the number of hairs in the growing phase is more constant, and the hair is less subject to age- and sex-related influences. Hair strands are cut as close as possible from the scalp, and their location on the scalp must be noted. Once collected, hair samples may be stored at ambient temperature in aluminum foil, an envelope, or a plastic tube. The sample size taken varies considerably among laboratories and depends on the drug to be analyzed and the test methodology. For example, when fentanyl or buprenorphine are investigated, a 100-mg sample is recommended. Sample sizes reported in the literature range from a single hair to 200 mg, cut as close to the scalp as possible. When sectional analysis is performed, the hair is cut into segments of about 1, 2, or 3 cm, which corresponds to about 1, 2, or 3 months' growth.

10.5.1.2 Decontamination Procedures

Contaminants of hair would be a problem if they were drugs of abuse or their metabolites or if they interfered with the analysis and interpretation of the test results. It is unlikely that anyone would intentionally or accidentally apply anything to their hair that would contain a drug of abuse. The most crucial issue facing hair analysis is the avoidance of technical and evidentiary false positives. Technical false positives are caused by errors in the collection, processing, and analysis of specimens, while evidentiary false-positives are caused by passive exposure to the drug. Approaches for preventing evidentiary false positives due to external contamination of the hair specimens have been described.²

Most but not all laboratories use a wash step; however, there is no consensus or uniformity in the washing procedures. Among the agents used in washing are detergents such as shampoo, surgical scrubbing solutions, surfactants such as 0.1% sodium dodecylsulfate, phosphate buffer, or organic solvents such as acetone, diethyl ether, methanol, ethanol, dichloromethane, hexane, or pentane of various volumes for various contact times. Generally, a single washing step is used; although a second identical wash is sometimes performed. If external contamination is found by analyzing the wash solution, the washout kinetics of repeated washing can demonstrate that contamination is rapidly removed. According to Baumgartner and Hill,² the concentration of drug in the hair after washing should exceed the concentration in the last wash by at least ten times. It has also been

proposed that hair should be washed three times with phosphate prior to analysis to remove any possible external contamination and that the total concentration of any drug present in the three phosphate washes should be greater than 3.9 times the concentration in the last wash.

Detection of drug metabolites in hair, whose presence could not be explained by hydrolysis or environmental exposure, would unequivocally establish that internal drug exposure had occurred.³ Cocaethylene and nor-cocaine would appear to meet these criteria, as these metabolites are formed only when cocaine is metabolized. Because these metabolites are not found in illicit cocaine samples, they would not be present in hair as a result of environmental contamination, and thus their presence in hair could be considered a marker of cocaine exposure. This procedure can be extended to other drugs. However, there is still a great controversy about the potential risk of external contamination, particularly for crack, cannabis, and heroin when smoked as several authors have demonstrated that it is not possible to fully remove the drugs.^{4,5} In conclusion, although it is highly recommended to include a decontamination step, there is no consensus on which procedure performs best and each laboratory must validate its own technique.

10.5.1.3 Drug Solubilization

To determine the amount of a drug remaining in hair after washing, it is necessary to solubilize the drugs in the hair. Solubilization must be such that the analytes are not altered or lost. Care is necessary to prevent the conversion of cocaine to benzoylecgonine or 6-monoacetylmorphine to morphine, for example.

The hair sample can be pulverized in a ball-mill prior to testing, cut into segments, or the entire hair dissolved. The preparation techniques are generally based on one of the following procedures:

- Incubation in an aqueous buffer and analysis with immunological techniques, mostly RIA
- Incubation in an acidic or basic solution followed by liquid–liquid extraction or solid-phase extraction and analysis with chromatographic techniques, mostly GC/MS
- Incubation in an organic solvent (generally methanol with or without hydrochloric acid), liquid extraction or solid-phase extraction and analysis with chromatographic techniques, mostly GC/MS
- Digestion in an enzymatic solution, liquid extraction or solid-phase extraction and analysis with chromatographic techniques, mostly GC/MS

10.5.1.4 Drug Analysis

The first publication dealing with the analysis of morphine in hair for determining the history of opiate abuse reported the use of RIA.¹ This paper was followed by a great number of procedures, which mostly used RIA and/or GC/MS. Chromatographic procedures are a powerful tool for the identification and quantification of drugs in hair, owing to their separation ability and their detection sensitivity and specificity, particularly when coupled with MS. Proposed cutoff concentrations and expected concentrations for drugs of abuse in hair are presented in Table 10.5.1.

Table 10.5.1 Proposed Cutoff Concentrations (when tested by GC/MS) and Expected Concentrations for Drugs of Abuse in Hair

Drug	GC/MS Cutoff Concentration	Expected Concentrations
Heroin	0.5 ng/mg of 6-acetylmorphine	0.5–100 ng/mg, in most cases <15 ng/mg
Cocaine	0.5 ng/mg of cocaine	0.5–100 ng/mg, in most cases <50 ng/mg, in crack abusers >300 ng/mg is possible
Amphetamine, MDMA	0.5 ng/mg for both drugs	0.5–50.0 ng/mg
Cannabis	0.05 ng/mg for THC	THC: 0.05–10 ng/mg, in most cases <3 ng/mg
	0.5 pg/mg for THC-COOH	THC-COOH: 0.5–50 pg/mg, in most cases <5 pg/mg

Table 10.5.2 Screening Procedures for the Detection of Controlled Drugs in Hair (see Reference 9)

Method	Kauert	Moeller	Kintz
Analytes	Heroin, 6-MAM, dihydrocodeine, codeine, methadone, THC, cocaine, amphetamine, MDMA, MDEA, MDA	6-MAM, dihydrocodeine, codeine, methadone, THC, cocaine, amphetamine, MDMA, MDEA, MDA	6-MAM, codeine, methadone, cocaine, amphetamine, MDMA, MDEA, MDA, most pharmaceuticals
Decontamination step	Ultrasonic 5 min each 5 ml H ₂ O 5 ml acetone 5 ml petroleum ether	20 ml H ₂ O (2×) 20 ml acetone	5 ml dichloromethane (2 × 5 min)
Homogenization	100 mg hair cut into small sections in a 30-ml vial	Ball mill	Ball mill
Extraction	4 ml methanol, ultrasonic 5 h, 50°C	20–30 mg powdered hair, 2 ml acetate buffer + β-glucuronidase/aryl-sulfatase, 90 min/40°C	50 mg powdered hair, 1 ml 0.1 N HCl, 16 h/56°C
Clean-up	None	NaHCO ₃ ; SPE (C18), elution with 2 ml acetone/dichloromethane (3:1)	(NH ₄) ₂ HPO ₄ ; extraction 10 ml chloroform/2-propanol/ <i>n</i> -heptane (50:17:33); organic phase purified with 0.2 N HCl; HCl phase to pH 8.4; re-extraction with CHCl ₃
Derivatization	Propionic acid anhydride	1000 μl PFPA/75 μl PF- <i>n</i> -propanol; 30 min/60°C; N ₂ /60°C; 50 μl ethylacetate	40 μl BSTFA + 1% TMCS or HFBA; 20 min/70°C

Radioimmunoassay is the most common screening test for hair. Kits, generally designed for urine, can be used without any modification, at pH values above 7. Calibration curves are obtained either from the controlled urines in the kit or from extracts of drug-free hair samples spiked with the drugs. Duplicate determinations are recommended. The RIA results should be confirmed by GC/MS. In the absence of a second independent method, RIA detection must be interpreted with caution. However, even the high sensitivity of GC/MS is sometimes not sufficient to detect drugs, especially when starting with a small quantity of hair. For these reasons, it may be necessary to carry out immunological analysis of drugs in hair using RIA reagents that are specific for the selective estimation of a drug like fentanyl, lysergide (LSD), or buprenorphine.

Chromatographic methods have been used as screening and confirming tests. Moreover, they allow quantification of the drugs and drug metabolites. Some classic GC/MS procedures are given in detail in Table 10.5.2. There are very few papers that present data using high-performance liquid chromatography/MS (HPLC/MS), except for buprenorphine, diuretics, and corticosteroids.

10.5.1.5 Drug Identification

Opiates

As heroin samples always contain codeine, codeine is also detected in cases of heroin abuse. Morphine is a metabolite of codeine and can be detected when codeine is abused. The quantification of both drugs was proposed to differentiate between codeine and heroin abuse.⁶ If the morphine concentration is clearly higher than the codeine concentration in the hair sample, heroin or morphine abuse is highly probable. If the codeine concentration is higher than the morphine level, then it may be assumed that codeine has been ingested. However, the discrimination of heroin users from individuals exposed to other sources of morphine alkaloids can be achieved by identifying directly heroin or 6-monoacetylmorphine.^{7,8} In this case, alkaline hydrolysis must not be used in order to avoid hydrolysis. In most samples, it was demonstrated that 6-monoacetylmorphine concentrations

exceeded those of morphine, which is a less lipophilic compound. Other opioids have been detected, including dihydrocodeine, pholcodine, ethylmorphine, dextromoramide, methadone, fentanyl, sufentanyl, pentazocine, zipeprol, and buprenorphine.

Cocaine

Procedures for the detection of cocaine have been published in several papers.^{9,10} There is considerable variety in the workup and derivatization conditions. In most cases, cocaine is found in higher concentrations than benzoylecgonine and methylecgonine.^{11,12} The determination of the pyrolysis product of cocaine, anhydroecgonine methylester (AEME), is helpful to distinguish cocaine from crack users. Kintz found AEME in the range 0.2 to 2.4 ng/mg for seven crack users.¹³ An important study with controlled doses of cocaine-d₅ was published in 1996.¹⁴ The deuterium-labeled cocaine was administered intravenously and/or intranasally in doses of 0.6 to 4.2 mg/kg under controlled conditions. A single dose could be detected for 2 to 6 months; the minimum detectable dose appeared to be between 22 and 35 mg.

Amphetamines

Papers dealing with amphetamine and methamphetamine have been published.¹⁵ The workup (liquid–liquid extraction after acid or alkaline hydrolysis) and derivatization procedures (trifluoroacetic anhydride, TFA) are similar in most of the publications. After methamphetamine intake, its major metabolite, amphetamine, can be detected in hair samples and the differentiation between methamphetamine and amphetamine intake can be achieved by reviewing the ratio between the drugs. In 1992, methylenedioxy-*N*-methamphetamine (MDMA or ecstasy) was first detected in the hair of an abuser at the concentration of 0.6 ng/mg.¹⁶ In Europe, MDMA is one of the most frequently identified drugs. Since the first screening procedure in 1995, different methods have been published.^{17,18} These procedures permit the determination of amphetamine, methylamphetamine, methylenedioxyamphetamine, methylenedioxymethamphetamine, methylenedioxyethamphetamine, and *N*-methylbenzodioxazolybutanamine (MBDB) by electron impact GC/MS.

Cannabis

In 1995 the first results on cannabis in hair by using GC/MS and the determination in the same run of ⁹-tetrahydrocannabinol (THC) and its major metabolite 11-nor-⁹-THC carboxylic acid (THC-COOH) were reported.¹⁹ The measured concentrations were low, particularly in comparison with other drugs. Some authors suggested the use of negative chemical ionization²⁰ to target the drugs or the application of tandem mass spectrometry.²¹ More recently, a simpler method was proposed,²² based on the simultaneous identification of cannabinal (CBN), cannabidiol (CBD), and THC. This procedure is a screening method that is rapid, economic, and does not require derivatization prior to analysis. To avoid potential external contamination (as THC, CBD, and CBN are present in smoke), the endogenous metabolite, THC-COOH, should be looked for to confirm drug use. The concentrations measured are very low, particularly for THC-COOH (pg/mg range).

10.5.1.6 Place of Hair

Although there are still controversies on how to interpret the results, particularly concerning external contamination, cosmetic treatments, genetic considerations, and drug incorporation, pure analytical work in hair analysis has reached a sort of plateau, having solved almost all the analytical problems. Although GC/MS is the method of choice in practice, GC/MS/MS or LC/MS are today used in several laboratories, even for routine cases, particularly to target low-dosage compounds, such as THC-COOH, fentanyl, flunitrazepam, or buprenorphine. Electrophoretic/electrokinetic ana-

lytical strategies, chiral separation, or application of ion mobility spectrometry constitute the latest new developments of the analytical tools reported to document the presence of drugs in hair. Quality assurance is a major issue of drug testing in hair. Since 1990, the National Institute of Standards and Technology (Gaithersburg, MD) has developed interlaboratory comparisons, recently followed by the Society of Hair Testing (Strasbourg, France). At the moment, some laboratory guidelines concerning hair analysis are under preparation, both by the U.S. Substance Abuse Mental Health Services Administration (SAMHSA) Mandatory Guidelines and the Society of Hair Testing; however, final publication has not yet materialized.

By providing information on exposure to drugs over time, hair analysis may be useful in verifying self-reported histories of drug use in any situation in which a history of past rather than recent drug use is desired, as in pre-employment and employee drug testing. In addition, hair analysis may be especially useful when a history of drug use is difficult or impossible to obtain, such as from psychiatric patients. During control tests of hair fragments, a drug addict is not able to hide the fact that drugs have been used whereas intermittent drug use may be difficult to detect if urine or blood tests alone are undertaken, even when the tests are repeated. There are essentially three types of problems with urine drug testing: false positives when not confirmed with GC/MS, the embarrassment associated with observed urine collection, and evasive maneuvers, including adulteration. These problems can be greatly mitigated or eliminated through hair analysis. It is always possible to obtain a fresh, identical hair sample if there is any claim of a specimen mix-up or breach in the chain of custody. This makes hair analysis essentially fail-safe, in contrast to urinalysis, since an identical urine specimen cannot be obtained at a later date.

Another potential use of hair analysis is to verify accidental or unintentional ingestion of drinks or food that has been laced with drugs. In case of a single use, the hair will not test positive. For example, ingestion of poppy seeds appears to be sufficient for the creation of a positive urine result, while ingestion of up to 30 g of poppy seeds did not result in a positive hair identification (Sachs, personal communication, 1994). The greatest use of hair analysis, however, may be in identifying false negatives, since neither abstaining from a drug for a few days nor trying to "beat the test" by diluting urine will alter the concentration in hair. Urine does not indicate the frequency of drug intake in subjects who might deliberately abstain for several days before drug screenings. While analysis of urine specimens cannot distinguish between chronic use and single exposure, hair analysis offers the potential to make this distinction.

10.5.2 Oral Fluid

Oral fluid has been increasingly used as an analytical tool in pharmacokinetic studies, therapeutic drug monitoring, and the detection of illicit drugs. More recently, particular interest in oral fluid has been expressed by law enforcement agencies for roadside testing of intoxicated drivers or in occupational medicine. The presence of metabolites of drugs in urine of potentially impaired drivers can be interpreted as evidence of relatively recent exposure, except for cannabis. However, this does not necessarily mean that the subject was under the influence at the time of sampling. It has been claimed that the concentrations of many drugs in oral fluid correlate well with blood concentrations, which suggests that qualitative measurements in saliva may be a valuable technique to determine the current degree of exposure to a definite drug at the time of sampling.

10.5.2.1 Oral Fluid Sampling

Several methods have been described for the collection of mixed saliva. Based on a recommendation of a working group of the Drug Testing Advisory Board in the U.S., the term *oral fluid* is preferred. Saliva stands for the secretion of the salivary glands, while the testing fluid also contains mucosal transsudate and crevicular fluid.

Oral fluid is usually collected by spitting into a collection vial or wiping the oral cavity with a swab. Many different stimuli will cause salivation. Spitting itself is usually a sufficient stimulus to elicit a flow of about 0.5 ml/min. However, there are a number of limitations: in an on-site situation "dry mouth" was often reported;¹ moreover, the salivary flow is decreased after intake of certain drugs, e.g., some tricyclic antidepressants and amphetamines. Individuals often collect more froth than actual liquid providing a viscous sample with a small sample size, which com-

plicates the analysis. Many researchers have found it advantageous to stimulate salivation by placing sour candy or citric acid crystals in the mouth prior to collection, or chewing an inert material like Teflon. Substances like Parafilm® should be avoided because they may absorb highly lipophilic drugs. The individual should allow saliva to accumulate in the mouth and then expectorate into a suitable container. Some special devices have been designed to facilitate the sampling of saliva. The use of a dental cotton roll to collect saliva has been improved and is nowadays available as the Salivette® (Sarstedt, Germany). Other commercialized devices include Accu-sorb®, SmartClip®, and Intercept®.

The effect of collection methods on drug concentrations in oral fluid is not well described in the scientific literature. However, caution has to be taken. As the oral fluid flow rate increases, the concentration of bicarbonate ions increases. This may alter the saliva–plasma ratio in a pH-dependent manner, especially for weakly basic drugs with a pK_a approaching the oral fluid pH, e.g., cocaine and opioids.² Kato et al.³ observed that the concentrations of cocaine, benzoylecgonine, and ecgonine methylester were substantially greater in nonstimulated mixed saliva than after stimulation with citric acid. A controlled clinical study designed to determine the effects of selected collection protocols on oral fluid codeine concentrations was published recently.⁴ Concentrations at different time points averaged 3.6 times higher after spitting without stimulation (= control method) than with acidic stimulation. The control method showed 1.3 to 2.0 times higher concentrations than concentrations in specimens collected by chewing a sugarless gum or using the Salivette or the Finger Collector containing Accu-Sorb® (Avitar Technologies Inc., Canton, MA, U.S.A.). A second issue influencing the use of oral fluid as a drug testing matrix is the contamination of the buccal cavity depending on the route of administration, e.g., for several hours after smoking or sniffing certain drugs. After smoking a cannabis cigarette, the cannabinoids in the smoke are sequestered in the mouth. THC concentrations obtained after direct extraction of a Salivette (positioned between gum and cheek for 1 to 2 min) exceeded the concentrations of THC in samples obtained by spitting by a factor 10 to 100.

10.5.2.2 Screening Tests for Oral Fluid

Before oral fluid can be used for rapid screening and especially for on-site testing, the following criteria should be met: (1) a fast, simple, and validated sampling procedure; (2) a test that needs a small sample volume (100 µl); (3) an antibody targeted to the parent molecules rather than the metabolites; (4) a sensitivity adapted to the expected concentrations in oral fluid; (5) screening cutoff values that meet the requirements for high sensitivity and specificity; (6) an electronic reader.

Some prototypes of on-site tests have been investigated during the course of the ROSITA project.⁵ Unfortunately, none of the present devices is satisfactory in terms of sensitivity and reliability. However, many development efforts are under way and the involved companies are improving the ease of use and the accuracy of their tests.

The results of the first large-scale database on oral fluid testing in private industry were published in 2002.⁶ About 77,000 specimens were screened by the Intercept immunoassay at manufacturer's recommended cutoff values for five drug classes (cannabis, opiates, amphetamines, cocaine, and phencyclidine). Presumptive positive specimens were confirmed by GC/MS/MS.

The screening cutoffs will depend on the specificity of the antibodies, and the presence of other cross-reacting metabolites in oral fluid. Quite recently, SAMHSA cutoff values have been proposed for the screening and confirmation of most illicit drugs in oral fluid.

10.5.2.3 Analytical Procedures

Oral fluid can be extracted and analyzed as other biological fluids such as blood. In general, there will be less interference from endogenous compounds than with blood or urine. An oral fluid sample collected with a special device usually provides the analyst with a clean specimen. However,

a sample collected by spitting contains cell debris, food particles, and strings of mucus; centrifugation is difficult because of the high viscosity. The specimen has to be stored at -4°C and measured as soon as possible because of possible bacterial and fungal growth. The cocaine concentration in saliva, stored in a plastic recipient without addition of citric acid or other stabilizers, remains unaltered at -4°C for 1 week. Freezing of the sample lowers the viscosity substantially so that centrifugation can be performed after thawing. This ensures better handling of the sample and a high stability for most analytes for a long period of time except for THC. Sometimes, the addition of sodium fluoride is reported, e.g., for cannabis and benzodiazepines.

A selection of various chromatographic procedures for drugs of abuse in saliva has been published recently.² Quantitation is usually performed with the common GC/MS procedures for drugs of abuse in blood, using electron impact mode and the appropriate deuterated standards. Since oral fluid contains the parent drugs, it is important to add internal standards for the quantification of THC, cocaine, and 6-MAM. Due to the smaller sample volume of an oral fluid specimen in comparison to a blood sample, analytical procedures using MS in chemical ionization mode, tandem MS/MS confirmation, or LC-MS are being developed.

Amphetamines

It has been shown recently¹ that the concentrations of amphetamine and MDMA in oral fluid, either obtained by spitting or with a Salivette, exceed the corresponding plasma concentrations 10 to 100 times. Oral contamination after sniffing of the drug can account for only some of the high concentrations during the first hours. Oral fluid samples can also be extracted using the common solid-phase extraction procedures for amphetamines in blood. Proposed SAMHSA screening cutoff values are 50 ng/ml for D-methamphetamine as the target analyte and confirmation cutoff values are 50 ng/ml for D-amphetamine and 50 ng/ml for D-methamphetamine.

A first innovative approach to the problem of low sample volumes is the use of LC-MS-MS with a minimum sample workup. Detection limits are in the range of 2 ng/ml for amphetamine and the designer amphetamines, using only 50 μl of oral fluid.⁷ A simple precipitation of the proteins with methanol followed by centrifugation or even dilution of the saliva sample followed by direct injection allows the analyst to process a high number of oral fluid samples with a small sample size.

Cannabis

Although there is very little transport for THC from blood to saliva, the usual administration routes (smoking, ingestion) provide detectable levels of THC for several hours with different techniques (HPLC, GC-ECD, GC-MS; limit of quantification 1 to 20 ng/ml). It is obvious that the higher THC concentrations after smoking are due to contamination of the buccal cavity. Calculation of S/P ratios in these circumstances is of little value but the detection of cannabinoids in saliva is a better indication of recent use than detection of the metabolite in urine.

The analytes of interest are THC, cannabinol, and cannabidiol.¹ SAMHSA proposes a screening cutoff of 4 ng/ml for THC as the target analyte for the initial screen and 4 ng/ml of THC in the confirmation analysis. Extraction from an oral fluid sample can be done with a mixture of hexane/ethylacetate (9/1) (v/v) after acidification; derivatization is performed by methylation with tetramethylammoniumhydroxide and iodomethane and subsequent extraction into isooctane. The limit of detection can be increased by pulsed splitless injection of 4 μl of the derivatized extract; linearity is observed in the range 0.5-50 ng/ml, with a LOD of 0.1 ng/ml.

It has been demonstrated⁸ that the cotton from the Salivette adsorbs 90% of the THC content of a spiked saliva sample. After centrifugation, no THC could be detected in the recovered fluid. Extraction of the dry cotton with methanol or with hexane/ethylacetate (9/1) (v/v) after addition of THC-d_3 to the roll resulted in THC concentrations exceeding 100 ng/salivette in drivers showing impairment and providing a positive blood sample.⁵

Cocaine

Numerous reports have documented the excretion of cocaine and metabolites in saliva. Cocaine appeared in saliva rapidly following intravenous injection, inhalation, and intranasal administration to volunteers. Contamination of the oral cavity after smoking and sniffing was variable but significant during the first 2 h after dosing. Anhydroecgonine methyl ester was detectable in saliva after smoking, but it was quickly cleared. Benzoylecgonine and ecgonine methyl ester levels were only comparable with cocaine concentrations at times when those had declined to below 100 ng/ml. However, the concentrations of the metabolites will be higher in chronic users. Proposed SAMHSA screening cutoff values are 20 ng/ml for benzoylecgonine as the target analyte, 8 ng/ml for the confirmation.

Generally, cocaine and its metabolites can be detected in saliva using a simple solid-phase extraction procedure: the sample is diluted with acetate buffer pH 4.0 and brought on a conditioned Bond Elut Certify[®] column; washing is performed with water, buffer pH 4.0, and acetonitrile, and elution occurs with dichloromethane/isopropanol/ammonia (80/20/2) (v/v/v). Replacing the buffer with 0.1 N HCl allows a washing step with methanol instead of acetonitrile because of the ionic binding of benzoylecgonine to the column. Derivatization is often performed with BSTFA but pentafluoropropionic anhydride in combination with pentafluoropropanol provides a better sensitivity for benzoylecgonine. Limits of detection are in the range 1 to 5 ng/ml.

Opiates

Heroin is rapidly metabolized to 6-MAM in blood, which is in turn converted to morphine. After intravenous injection, the saliva/plasma ratio for heroin and 6-MAM can be lower than one, depending on the salivary pH. After smoking or sniffing of heroin, the concentrations of the analytes in saliva remain higher than in plasma for 2 to 3 h due to a contamination of the buccal cavity. SAMHSA proposed cutoff values are 40 ng/ml morphine for the initial screen and 40 ng/ml of morphine and 4 ng/ml of 6-MAM for the confirmation. Detection of morphine, codeine, and 6-MAM in saliva is based on similar analytical procedures as for cocaine. However, a washing step with a strong acid will result in the hydrolysis of 6-MAM, so acetate buffer pH 4.0 is preferred for opioids. GC-MS data after silylation show similar results as for the PFP derivatives.

Codeine was detected in oral fluid for 12 to 24 h after oral intake of 30 mg of liquid codeine phosphate depending on the individual and on the collection protocol.⁴ After solid-phase extraction, derivatization occurred with TFAA and GC-MS analysis was performed using positive-ion chemical ionization. The limit of quantification was 5 ng/ml, limit of detection 1.0 ng/ml. Substantially different pharmacokinetic parameters were detected after spitting, with or without stimulation, using a Salivette or the Finger collector containing Accu-Sorb[®]. Moreover, *in vitro* studies showed that more than 90% of codeine and morphine could be recovered from the Salivette after centrifugation and only 60% from the Finger collector after milking the foam.

10.5.3 Sweat

Researchers have known for more than a century¹ that drugs are excreted in sweat. Although it is still poorly understood how nonvolatile chemicals exit the body through the skin, significant advances in sweat analyses have been made during the past few years with the development of the sweat-patch technology.² Over a period of 1 to 7 days, sweat will saturate the pad located in the center of the patch and will slowly concentrate, and drugs present in the perspiration fluid will be retained. Sweat appears to offer the advantage of being a non-invasive means of obtaining a cumulative estimate of drug exposure over 1 week. Sweat testing has found applications in monitoring of individuals in drug rehabilitation or in probation/parole programs.^{3,4}

The term *sweat-testing* is misleading, because drugs are not only excreted by sweat glands; the excretion of drugs through the skin is also possible by sebaceous glands or transdermal liquid transport.

Sweat is a liquid secreted by the sweat glands, originating deep within the skin. Water (99%) is the major component. Na⁺ and Cl⁻ are the major ions, present in variable concentrations, ranging from 5 to 80 mmol/L. Amino acids, biogenic amines, and vitamins are only present in trace amounts. The pH (4 to 6) is strongly associated with the amount of lactic acid excreted. Apocrine glands secrete a more viscous, cloudy, yellow-white liquid, which is primarily sterile and odorless, and rich in cholesterol (75%), triglycerides, and fatty acids (20%).

Sebaceous glands are associated with hair follicles and located everywhere except on palms and soles; they are particularly abundant on the scalp and forehead. They produce a viscous, yellow-white liquid oily sebum that consists of triglycerides (60%) and wax esters. Excreted sweat and sebum cannot be examined separately.

Sweat secretion is an important homeostatic mechanism for maintaining a constant core body temperature. At temperatures above 31°C, body heat is dissipated by the release of sweat on the skin surface resulting in evaporative heat loss. Between 300 to 700 ml/day of *insensible* sweat is produced over the whole body, likely caused by diffusion through the skin, whereas 2 to 4 L/h of *sensible* sweat may be produced for short periods by extensive exercise. The amount of sweat that is produced is thus affected by body location, ambient temperature, body temperature, and relative humidity of the environment and by emotional, mental, and physical stress. The variability of these factors and the uneven distribution of the sweat glands make it difficult to obtain specimens of sweat systematically.

10.5.3.1 Sweat Collection

Almost all studies obtain mixed secretions of sweat and sebum, which is incorrectly referred to as sweat. Methods to collect drugs in sweat have included the use of gauze, cotton, towel, or filter paper to absorb sweat and the collection of liquid sweat in rubber gloves or plastic body bags.^{2,5} Thermal⁶ or pharmacological stimulations such as with pilocarpine⁷ were proposed to secrete an unusually large amount of sweat.

Patches, similar to bandages, have been developed to wear for extended periods of time. Early patches were made of absorbent cotton pads sandwiched between a waterproof, polyurethane outer layer and a porous inner layer that is placed against the skin. They have been successfully applied to the detection of ethanol in sweat.⁸

Significant advances have been made during the past few years to develop a non-occlusive sweat collection device, which has been marketed as the PharmChek™ sweat patch. The device consists of an adhesive layer on a thin transparent film of surgical dressing to which a rectangular absorbent pad is attached. The sweat patch acts as a specimen container for nonvolatile and liquid components of sweat, including drugs. Nonvolatile substances from the environment cannot penetrate the transparent film, which is a semipermeable membrane over the pad that allows oxygen, water, and carbon dioxide to pass through the patch, leaving the skin underneath healthy. Over a period of 1 to 10 days, sweat saturates the pad and the water content of the perspiration is volatilized by the body's heat; drugs present in sweat are retained. The region of the skin where the patch will be applied is thoroughly decontaminated with 50% of isopropanol. Subjects can wear one patch with minimal discomfort for at least 1 week. Normal hygiene practices can be achieved. Attempts to remove the patch prematurely are readily visible to personnel trained to monitor the sweat patch.

An alternative collection for epidemiological surveys and for testing of potentially impaired drivers consists of wiping the skin with a cosmetic pad moistened with isopropanol.⁹ This procedure allows rapid collection of drugs that may arise both from sweat evaporating on the surface of the skin and from external contamination.

10.5.3.2 Drug Detection without a Patch Collection

By using some of the early "home-made" collection methods, it was possible to identify various drugs, including methadone, phenobarbital, morphine, cocaine, THC, and methamphetamine.¹⁰ Sweat samples that are collected on gauze or cotton by wiping the surface of the skin are eluted with water and extracted by liquid-liquid methods.

Kidwell et al.¹¹ investigated an alternative collection of sweat to detect cocaine prevalence in a university population. Sampling of hands and forehead was performed with a cotton pad (skin wipe) moistened with 500 µl of 90 or 70% isopropanol. LODs of the GC-MS-CI confirmatory method were 1.2 to 2.2 ng/wipe for cocaine and benzoylecgonine. A skin swab test may provide a rapid way to gather data on drug use/exposure in a certain population without the embarrassment often felt when obtaining urine samples and the concern for cosmetic damage often expressed when individuals are asked to take hair samples. Skin wipes detect drugs excreted in sweat/sebum more rapidly than a device (patch) that needs to collect pure sweat over an extended period of time.

Sweat, as a forehead specimen, was obtained from injured drivers⁹ by wiping the forehead with a commercial pad spiked with 0.5 ml of water/isopropanol (50:50). After extraction of the pad with hexane/ethyl acetate (90:10) and methylation, THC was detectable by GC/MS between 4 to 152 ng/pad, with the risk of environmental contamination. Neither 11-hydroxy-THC nor THC-COOH was identified.

10.5.3.3 Drug Detection with a Patch Collection

Controlled experimental studies using the Pharmchek™ sweat patch have been performed for cocaine,^{2,12} heroin,¹³ and amphetamine derivatives, such as methamphetamine,¹⁴ MBDB,¹⁵ and MDMA.¹⁶

Administration of low doses of cocaine (about 1 to 5 mg) produced detectable amounts of cocaine in sweat.¹² Sweat patches were applied to the back and abdomen of subjects prior to and periodically after drug administration. Before affixing the patches, the skin area was cleaned with an isopropyl alcohol (70%) swab. The absorbent pad was extracted with 2.5 ml of a mixture of 0.1% Triton X-100 in 0.2 M acetate buffer, in the presence of deuterated internal standards. After agitation and centrifugation, the filtered extract solution was purified by SPE and submitted to GC/MS. LODs for cocaine and metabolites were approximately 1 ng/patch. Within- and between-

run coefficients of variation were less than or equal to 10%. It was observed that the parent drug was the predominant analyte with cocaine levels (ng/patch) being much higher than the concentrations of the metabolites benzoylecgonine and ecgonine methyl ester. After a single 25-mg IV injection, 42-mg smoked, and 32-mg intranasal administration, cocaine appeared in sweat within 2 h after drug administration and peaked within 24 h with maximum concentrations varying from as low as 15 to as high as 70 ng cocaine/patch. Inter-subject variability was high whereas intra-subject variability was relatively low.

More recent work has focused on the applications of the "Fast Patches" requiring only 30 min for sweat collection because they employ heat-induced sweat stimulation and a larger cellulose pad for increased drug collection.² Sweat was collected periodically for 48 h following subcutaneous administration of 75 or 150 mg of cocaine hydrochloride/70 kg. Torso Fast Patches were applied to the abdomen or flank, and Hand-held Fast Patches were affixed to the palm of the nondominant hand and elution of the patch was performed with 0.5 M sodium acetate buffer (pH 4.0). Peak cocaine concentrations (4.5 to 24 h after dosing) ranged from 33 to 3579 ng/patch for the Hand-held Patch and from 22 to 1463 ng/patch for the Torso Fast Patch. Cocaine could be detected for at least 48 h after dosing. Drug concentrations were considerably higher than those reported for the Pharmchek sweat patch. Cocaine concentrations in the Hand-held Patch were more than twofold greater than those found in the Torso Fast Patch.

In a study conducted during a heroin maintenance program, 14 subjects were injected with two or three doses of heroin hydrochloride ranging from 80 to 1000 mg/day. The sweat patches were applied before the first dosage and removed after 24 h, minutes before the next dosage.¹³ Patches were extracted with acetonitrile before GC-MS analysis. Concentrations (ng/patch) ranged from 2.1 to 96.3 for heroin, 0 to 24.6 for 6-MAM, and 0 to 11.2 for morphine. There was no correlation between the doses of heroin administered and the concentrations of heroin measured in sweat.

An enzyme immunoassay screening test was described for methamphetamine in eluates of sweat patches, with a cross-reactivity of 144% for MDMA, 30% for amphetamine, and 21% for MDA. Diagnostic sensitivity and specificity were 84.5 and 93.2%, respectively, when comparing to the GC-MS results and applying a cutoff value of 10 ng/ml amphetamine equivalents (using methamphetamine calibrators). The clinical sensitivity and specificity of the overall analysis system were 85 and 100%, respectively, using known methamphetamine dosing of volunteers as the reference standard. Drug doses given were probably lower than a street drug dose.¹⁴

N-Methyl-1-(3,4-methylenedioxypheyl)-2-butanamine (MBDB) was detected in the methanolic extract from the Pharmchek sweat patch with concentrations increasing during the first 36 h following a single dose of 100 mg MBDB.¹⁵ Peak concentrations of MBDB and its metabolite 3,4-methylene-dioxypheyl-2-butanamine (BDB) were 44 and 23 ng/patch, respectively.

In a recent study,¹⁶ sweat was collected for up to 24 h with the PharmChek sweat patches from recreational users of MDMA who received a single 100-mg dose of the drug. After SPE and derivatization, analytes were tested by GC/MS. MDMA was detected in sweat as early as 1.5 h after administration and peaked at 24 h. In all the nine subjects, an on-site test with the Drugwipe immunochemical strip test was positive at 1.5 h.

As a result of the poor passive diffusion from plasma, it was necessary to use very sensitive techniques to detect some drugs in sweat. Ion trap GC/MS/MS was reported as useful for cannabis.¹⁷ THC was identified in sweat of nine cannabis users after wearing a patch for 5 days (4-38 ng/patch).³

10.5.4 General Conclusion

It appears that the value of alternative specimen analysis for the identification of drug users is steadily gaining recognition. This can be seen from its growing use in pre-employment screening, in forensic sciences, and in clinical applications.

Saliva and sweat will probably be used in the near future in roadside testing both for epidemiological and screening purposes.

Hair analysis may be a useful adjunct to conventional drug testing in toxicology. Methods for evading urinalysis do not affect hair analysis.

Specimens of saliva or sweat can be more easily obtained with less embarrassment than for urine, and hair can provide a more accurate history of drug use. However, due to a lack of suitable screening tools, costs are too high for routine use (because the analyses require hyphenated chromatographic procedures) but the generated data are extremely helpful to document positive urine cases. These new matrices may find useful applications in the near future, for example, in occupational medicine, roadside testing, or doping control or for law enforcement agencies to document illicit drug use.

10.6 INTERPRETING ALTERNATIVE MATRIX TEST RESULTS

Edward J. Cone, Ph.D.,¹ Angela Sampson-Cone, Ph.D.,¹ and Marilyn A. Huestis, Ph.D.^{2*}

¹ ConeChem Research, Severna Park, Maryland

² Chemistry and Drug Metabolism Section, Intramural Research Program, National Institute on Drug Abuse, National Institutes of Health, Baltimore, Maryland

10.6.1 Drug Testing with Alternative Matrices

Significant advances in analytical technology over the last decade have provided the analytical toxicologist with the means of testing for drugs of abuse and their metabolites in biologic matrices with ultrahigh sensitivity and specificity. Conclusive identification and measurement of drug residues in tissues provide important information on an individual's past drug use and exposure history. Such evidence can be important in many types of forensic investigations, e.g., workplace testing, accident investigations, health assessments, diagnosis, treatment and monitoring of drug abusers, and whether drug use was a contributory factor in civil and criminal acts. Many centrally acting drugs produce significant physiologic and behavioral impairment. Frequently, when accidents and loss of life and property occur, medical personnel and toxicologists are called upon to interpret toxicology results. This evidence may support or refute the presence of drug-induced behavioral changes in an individual. In addition, results may indicate whether drug use or drug exposure occurred, the frequency and route of drug use, and the probable level of exposure.

Many different types of biologic specimens can be tested for drug residues. The most frequently collected types are urine, oral fluid, sweat, hair, and blood. Circumstances often determine the type of specimen collected. Whereas post-mortem testing traditionally involves collection of blood and tissue specimens, accident and criminal investigations most frequently involve urine and blood. Workplace and treatment programs generally test urine specimens but, more recently, some have begun to test oral fluid, hair, and sweat as alternative or complementary specimens. Urine and sweat are utilized most commonly in the legal community, e.g., parolee monitoring.

The growing use of different biological specimens presents an array of challenges to those involved in forensic and clinical interpretation. The unique properties of each biological specimen offer somewhat different information on past drug use, and it is becoming increasingly important to understand these differences. In some cases, test results from diverse biological specimens may not agree. The reasons for agreement or disagreement may be complex. Forensic interpretation of specimen test results must be based on an understanding of the chemical and pharmacologic properties of the drug, performance characteristics of analytical methods, and the unique physiological properties of the biological specimens.

This chapter examines the similarities and differences of drug disposition in blood, urine, oral fluid, sweat, and hair specimens. The primary focus is on the chemical and physiologic properties of different specimens and the time course of drug disposition into and out of the biologic matrix. Differences in the physicochemical properties of drugs add to the complexity of interpretation of results. Cocaine is used as the primary model compound in this chapter to illustrate similarities and differences in specimen types. Understanding the "uniqueness" of drug disposition in biological matrices will guide interpretation of similar and disparate results from multiple biological specimens.

* Dr. Huestis contributed to this book in her personal capacity. The views expressed are her own and do not necessarily represent the views of the National Institutes of Health or the U.S. government.

Figure 10.6.1 Disposition of drug (D) and metabolite (M) in blood and tissues following active and passive drug administration and environmental exposure. The rate of excretion of drug and metabolite is indicated as “Very Fast” (minutes), “Fast” (minutes to hours), “Slow” (hours to days), and “Very Slow” (days to months). Abbreviations: D = drug; M = metabolite; D,M-Protein = protein-bound drug or metabolite; D, M-H⁺ = ionized drug or metabolite.

10.6.2 Drug Disposition in Alternative Matrices

10.6.2.1 Circumstances of Drug Exposure

Drug exposure takes place under many different circumstances. Active drug use can involve a variety of routes of administration including oral ingestion, inhalation, parenteral administration, and absorption through skin and mucosal membranes. Passive drug exposure can occur through inhalation of drug smoke, vapor, or dust, by external contamination of the skin, hair, and mucous membranes, and by oral ingestion, e.g., doping. “Active” drug administration is defined generally as intentional drug self-administration by the individual undergoing testing, whereas “passive drug exposure” is defined as unintentional drug exposure. Figure 10.6.1 provides a graphic illustration of the complex rate processes involved in drug use and exposure and in transfer into and out of different bodily tissues.

Regardless of how drug use or exposure occurs, the consequences of a positive test may be highly detrimental to the donor. Understanding how drugs penetrate and reside in different tissues is an important component in the development and use of biological specimens for drug testing.

10.6.2.2 Absorption and Distribution

During the process of penetrance into the body, drugs may be altered by metabolic and chemical processes. Drug metabolism that occurs during absorption, distribution, and elimination processes can result in the production of metabolites with substantially different properties than the parent drug. The pharmacologic activity of metabolites may be enhanced, reduced, or totally eliminated by molecular alteration. Once drug penetrance into the bloodstream occurs, the route of administration becomes less important to drug disposition. Depending on the chemical properties of the drug, metabolism may occur immediately in blood, but more commonly occurs following uptake

into the liver and other organs. Arterial blood carries drugs and metabolites to tissues and venous blood transports them away. The transfer of drug and metabolites into tissues is governed by factors such as the chemical properties of the drug, degree of tissue perfusion, protein binding, and characteristics of the tissue membrane. Drug uptake into tissues is generally rapid and equilibrium between highly perfused tissues and venous blood is quickly established. The rate of drug uptake is dependent on the rate of blood flow and the tissue/blood partition coefficient. Accumulation of drug by organ tissues occurs in the extracellular fluid. Some drugs also cross cell membranes into intracellular water. Long-term accumulation of lipid-soluble drugs may occur in fatty tissues.

10.6.2.3 Clearance and Elimination

Most drugs are cleared from the body through the processes of metabolism and excretion. The liver is the major site of drug metabolism and the type of metabolite produced is based on the enzymatic processes involved. A drug may be subject to hydrolytic cleavage, oxidation, reduction, and conjugation reactions, depending upon its molecular structure. Frequently, these reactions produce metabolites with greater water-solubility and less pharmacologic activity than the parent molecule. Such reactions primarily are irreversible and serve to clear active drug from the body. The enhanced water-solubility of metabolites facilitates their removal by excretory processes.

Nonvolatile drugs and metabolites are generally excreted in urine and feces. Other pathways of drug elimination include excretion in bile, saliva, sweat, milk (via lactation), sebum, other bodily fluids, skin (via desquamation), and hair. Some processes, such as excretion into bile and saliva, may be circulatory in nature and reabsorption into the bloodstream may occur during transit through the gastrointestinal tract.

10.6.3 Physiologic Considerations

10.6.3.1 Blood

Although blood is infrequently collected in workplace testing, it is important to understand drug disposition in this matrix. The primary mode of entry of drugs and metabolites into other biological specimens is from blood. On average, an adult human male weighing 70 kg has a blood volume of approximately 5 L. Blood is composed of two parts, plasma, the fluid portion, and formed elements that include blood cells and platelets that are suspended in the fluid. There are more than 60 proteins in plasma that fight infection, transport lipids, and prevent uncontrolled bleeding. Albumin is a major component of plasma protein and undergoes reversible binding with many drugs. Binding to protein has a major influence on a drug's disposition in the body. Protein-bound drug is a large molecular complex that cannot easily cross membranes. An equilibrium exists between protein-bound drug and free drug. Consequently, drug distribution to other tissues is limited to the portion of drug that exists as free unbound drug.

Drug molecules dissolved in blood are transported through a network of fine capillaries to the tissues. The rate of passage of drugs across cell membranes is dependent on the drug's chemical properties and the properties of the cell membrane. Capillary wall membranes are generally highly porous, whereas other membranes may be considerably more complex and less porous, e.g., unique endothelial cells of the blood-brain barrier and the multilayered epithelial cell layers of the dermis and epidermis. Lipid-soluble drugs generally diffuse more easily across membranes than polar, water-soluble drugs, metabolites, and highly protein-bound drugs.

Following drug absorption into the bloodstream, changes in blood concentrations initially reflect changes that occur as a result of distribution and uptake by tissues. At some point after administration, drug concentration in plasma approaches equilibrium with drug sequestered in tissues. Once

Figure 10.6.2 Plasma concentrations of cocaine in a subject (Subject I) after intravenous (IV), intranasal (IN), and smoked (SM) administration of single doses of cocaine.

equilibrium is established, drug concentration declines as a result of metabolic and elimination processes. Most drug concentrations decline at a rate proportional to the amount of drug remaining in the body. The elimination half-life ($t_{1/2}$) of a drug is the time required for the plasma concentration to be reduced by one half. The half-life of a particular drug generally is constant for an individual across a broad range of dosages; however, some drugs exhibit nonlinear kinetics when dosages overwhelm enzymatic and/or elimination processes.

An illustration of the decline of plasma cocaine concentrations of one subject (Subject I) following intravenous, intranasal, and smoked administration of 25 mg of cocaine hydrochloride is shown in Figure 10.6.2. Cocaine exhibited a plasma half-life of approximately 1.4 h after either intravenous or smoked administration. The decline in cocaine concentration following intranasal administration was biphasic, likely as a result of irregular absorption.

The appearance of drug metabolites in blood is influenced by the route of administration. The liver is the major site of drug metabolism. When drug is ingested, absorption of virtually all drugs is faster from the small intestine than from the stomach due to its large surface area. Therefore, gastric emptying is a rate-limiting step. The intraluminal pH is 4 to 5 in the duodenum, but becomes progressively more alkaline, approaching a pH of 8 in the lower ileum. Absorption of drugs from the gastrointestinal tract depends on the drug's ability to pass across intestinal cell membranes and resist destruction in the liver (first-pass effect). In most cases, drugs pass through intestinal membranes by simple diffusion, from an area of high concentration (inside the lumen) to an area of lower concentration (bloodstream). During absorption, significant metabolism may occur, so that only a fraction of the drug may survive intact. Metabolites formed in the liver may be excreted into the feces via bile, or may be released into the bloodstream at the same time as parent drug. Hence, following oral administration, the initial appearance of a metabolite in the bloodstream may be rapid with concentrations sometimes exceeding that of the parent drug.

Drug administration by other routes, e.g., parenteral, transmucosal, and inhalation, may partially or totally bypass the liver and avoid the "first-pass effect" of oral ingestion. Once drug enters the bloodstream, it is immediately distributed to all parts of the body. Approximately 25% of cardiac output is directed to the liver, where drug may be extracted from blood. A variety of processes may affect the ability of the liver to extract drug from blood, including the degree of drug-protein binding (only free, unbound drug may be extracted), solubility of the drug in the hepatic membrane, and metabolic processes occurring in the hepatocytes. Once formed, metabolite(s) may be transported into bile and released into the gastrointestinal tract or be returned to the bloodstream.

In contrast to oral administration, initial appearance of metabolites following parenteral and mucosal administration may be delayed. As an example, Figure 10.6.3 illustrates the appearance in plasma of cocaine and benzoylecgonine (BZE), a metabolite of cocaine, following intravenous administration. BZE was initially detected at 10 min and rose to a maximum concentration in

Figure 10.6.3 Plasma concentrations of cocaine (COC) and benzoylecgonine (BZE) in a subject (Subject I) after intravenous administration of a single 25-mg dose of cocaine.

approximately 1 h following cocaine administration. Thereafter, BZE declined slowly with an approximate half-life of 6.3 h. The rapid formation and slow disappearance of BZE relative to cocaine indicates that elimination, rather than metabolism, was the rate-limiting step for BZE. When the half-life of a metabolite is longer than that of the parent drug, accumulation of the metabolite can occur with repeated, frequent administrations, as occurs with BZE.

10.6.3.2 Urine

Approximately 20 to 25% of the blood from cardiac output, or 1200 mL/min, goes to the kidney. Blood enters the glomerulus for nonselective filtering of the plasma. Most drug molecules with low molecular weights can pass through the filter forming an ultrafiltrate with a concentration similar to plasma; however, only the unbound portion of the drug can be filtered. Consequently, drugs that are highly bound to plasma protein generally undergo a longer renal elimination period than drugs that are less highly bound. In addition, some drugs undergo active renal secretion, a carrier-mediated system. If the carrier has greater affinity for the free drug than plasma protein, then active renal secretion can increase the rate of elimination despite protein binding.

The glomerulus receives blood first and filters about 125 mL/min of plasma containing substances with molecular weights less than 20,000 Da. The plasma ultrafiltrate flows through the proximal convoluted tubule, loop of Henle, distal tubule, and continues through the collecting duct to the bladder. During transit through the nephron, electrolytes, nutrients, and water are reabsorbed and returned to the bloodstream. Excess water and waste products, such as urea, organic substances (including drugs and metabolites), and inorganic substances, are eliminated from the body. Normally, water is reabsorbed reducing urine flow to less than 1 to 2 mL/min. The daily amount and composition of urine vary widely depending upon many factors such as fluid intake, diet, health, drug effects, and environmental conditions. The volume of urine produced by a healthy adult in a 24-h period ranges from 1 to 2 L with a pH range of 5 to 7.5, but normal values outside these limits may be encountered.

As a consequence of extensive water reabsorption in the kidney, drugs and metabolites concentrate in urine. Indeed, if a drug or metabolite exists largely in the unbound state in plasma, its relative concentration could be up to 100 times greater in urine. Figure 10.6.4 illustrates the concentrations of cocaine and BZE in urine compared to plasma in a subject following intravenous administration of cocaine. Urine cocaine and BZE concentrations were approximately 15 and 100 times higher than in plasma, respectively. These findings suggest that BZE is less highly bound to protein than cocaine or alternately that cocaine is reabsorbed by the kidney during renal excretion. It is important to note that despite the large concentration differences observed in plasma as compared to urine, estimation of elimination half-lives were similar for both drugs in plasma and urine.

Figure 10.6.4 Plasma (PL) and urine (UR) concentrations of cocaine (COC) and benzoylecgonine (BZE) in a subject (Subject I) after intravenous administration of a single 25-mg dose of cocaine.

10.6.3.3 Oral Fluid

Oral fluid is a composite specimen that consists primarily of saliva, gingival crevicular fluid (fluid from the gingival crevice), and cellular debris. The bulk of fluid in the oral cavity originates from the submandibular and parotid glands and gingival crevicular fluid. During resting conditions, about 71% of oral fluid is supplied by the submandibular glands, approximately 25% originates from the parotid glands, and the remaining 4% is produced by other minor glands.¹ With stimulation, the fluid contribution from the parotid gland rises to about 41%. Salivary glands are innervated by both sympathetic and parasympathetic nerves. Saliva production occurs in response to neurotransmitter release. The volume of saliva varies considerably from approximately 500 to 1500 mL/day. The pH of saliva is generally acidic, but may range from 6.0 to 7.8, depending on the rate of saliva flow. As saliva flow increases, levels of bicarbonate increase, thus increasing pH.²

Saliva glands, as they are highly perfused, have a high blood flow. Drug in plasma is distributed rapidly to salivary glands and may appear in saliva within minutes of parenteral drug administration.³ Figure 10.6.5 illustrates the rapid appearance of cocaine and BZE in oral fluid compared to plasma. Cocaine concentrations in oral fluid generally exceeded those of plasma by a factor of approximately two. The acidic nature of oral fluid compared to plasma and cocaine's lipophilicity favor excretion in oral fluids and account for its higher concentration. BZE also appeared in oral fluid simultaneously with its appearance in plasma, but was present at approximately one third of its plasma concentration. The greater water solubility and lower lipid solubility of BZE apparently accounts

Figure 10.6.5 Plasma (PL) and oral fluid (OF) concentrations of cocaine (COC) and benzoylecgonine (BZE) in a subject (Subject I) after intravenous administration of a single 25-mg dose of cocaine.

for its lower concentration in oral fluid relative to plasma. However, the longer half-life of BZE compared to cocaine leads to prolonged appearance in oral fluid, in this case, exceeding the concentration of cocaine within 4 to 6 h. With multiple cocaine doses and accumulation of BZE, testing for BZE in oral fluid is likely to be of greater utility for the detection of cocaine use.

Other drugs of abuse such as opiates, amphetamines, phencyclidine, and designer drugs that contain basic nitrogen moieties exhibit similar distribution patterns in oral fluid compared to plasma.⁴ In contrast, tetrahydrocannabinol (THC), the major active ingredient of cannabis, is a non-nitrogen-containing compound that is highly fat soluble. Deposition of THC in the oral cavity during smoking and oral ingestion most likely accounts for its presence in oral fluid. Fortunately, the residence time of THC in the oral cavity is sufficient for detection over a similar time course as its presence in plasma. Indeed, detection rates for cannabis use by oral fluid testing appear to be similar to those seen in urine testing.⁵

10.6.3.4 Sweat

Sweat secretion is an important mechanism for maintaining a constant core body temperature. Following sympathetic nerve stimulation, sweat is excreted onto the surface of the skin and evaporated to release body heat. Sweat is secreted from two types of sweat glands: eccrine and apocrine glands. These glands originate deep within the skin dermis and terminate in excretory ducts emptying onto the skin or developing hair follicles. Eccrine glands are located on most skin surfaces, while apocrine glands are restricted to skin of the axilla, genitalia, and anus. Water is the primary constituent of sweat accounting for approximately 99% of its bulk,⁶ and sodium chloride is the most concentrated solute. Sweat also contains albumin, gamma globulins, waste products, trace elements, drugs, and many other substances found in blood. The rate of sweating is highly dependent on the environmental temperature. Above 31°C, humans begin to sweat and may excrete as much as 3 L/h over short periods of time. The average pH of sweat of resting individuals is reported to be 5.82.⁷ Following exercise, the pH increases with increasing flow rates and is reported to be between 6.1 and 6.7.⁸ Approximately 50% of sweat is generated by the trunk of the body, 25% from the legs, and the remaining 25% from the head and upper extremities.⁸

Blood flow delivers drug and metabolite to sweat glands, i.e., eccrine and apocrine glands, where diffusion of unbound drug and metabolite occurs through membranes. The rate of passage of drug from blood to sweat via the sweat gland epithelium appears to be proportional to the oil/water partition coefficient of the unionized drug.⁹ This process would be facilitated for drugs that demonstrate low degrees of ionization at physiological pH. For lipid-soluble, basic drugs with high pK_a values, excretion in sweat is further enhanced by the acidic nature of sweat. For example, cocaine generally is excreted in sweat in higher concentrations than found in plasma. Figure 10.6.6 illustrates the excretion of cocaine in sweat following intravenous, intranasal, and smoked routes of administration. Plasma cocaine concentrations are also shown following intravenous administration. After 2 h, sweat cocaine concentrations were considerably higher in sweat than in plasma. Despite the longer half-life of BZE, it was present in only trace concentrations (not shown).

10.6.3.5 Hair

Hair consists of five morphological components: cuticle, cortex, medulla, melanin granules, and cell membrane complex. Each is distinct in morphology and chemical composition. The number of human head hair follicles ranges from 80,000 to 100,000 follicles, but this decreases with age.¹⁰ Hair follicles are embedded in the dermis of skin and are highly vascularized to nourish the growing hair root or bulb.¹¹ The bulb at the base of the follicle contains matrix cells that give rise to the layers of the hair shaft including the cuticle, cortex, and medulla. Matrix cells undergo morphological and structural changes as they move upward during growth to form different layers of the hair shaft. These layers can often be distinguished by qualitative and quantitative differences in

Figure 10.6.6 Sweat (SW) patch concentrations of cocaine in a subject (Subject I) after intravenous (IV), intranasal (IN), and smoked (SM) administration of single doses of cocaine. For comparison, plasma (PL) cocaine concentrations after IV administration are also shown (dotted line). Sweat patches were applied and removed between each collection point.

their proteins and pigments.¹⁰ Hair is composed of approximately 65 to 95% protein, 1 to 9% lipid, and small quantities of trace elements, polysaccharides, and water.¹¹ The durability and strength of the hair shaft is determined by the proteins synthesized within the matrix cells. Matrix cells also may acquire pigment or melanin during differentiation into individual layers of hair. The pigment present in hair cells determines the color of the hair shaft. The primary structure of hair consists of two or three α -keratin chains wound into strands called microfibrils. Microfibrils are organized into larger bundles of macrofibrils that comprise the bulk of the cortex. Hair strands are stabilized and shaped by disulfide and hydrogen bonds giving the microfibrils a semi-crystalline structure. Cytochrome P450 and other enzymes have been identified in the hair follicle providing evidence that drug metabolism may occur within this structure; however, as hair becomes fully keratinized in 3 to 5 days, this capability is presumed to be greatly reduced.¹¹

A protective layer of epithelial cells called the cuticle surrounds the cortex. The cuticle is the outermost layer of hair, the innermost region is the medulla, and the hair cortex lies between these components. The overlapping cuticle cells protect the cortex from the environment. As hair ages, there is a gradual degeneration of the cuticle along the shaft due to exposure to ultraviolet radiation, chemicals, and mechanical stresses. The cuticle may be partially or totally missing in cases of damaged hair.¹² Hair damaged by cosmetic treatments and/or ultraviolet radiation may influence the deposition and stability of drug in the hair.¹³

Hair follicles continue to grow for a number of years and undergo different phases during a normal growth cycle of several years. Approximately 85 to 90% of the hair is in the anagen or growth phase at any single time.¹⁰ A small portion of mature hair then enters the catagen phase, in which there is a rapid reduction in growth rate. This phase lasts for a period of 2 to 3 weeks and is immediately followed by the telogen phase, the resting phase of hair. During this phase, no growth occurs. Approximately 10 to 15% of head hair is usually in the telogen phase. The hair strand may not be shed for several months prior to replacement by a new strand. Hair growth rates vary according to body location, sex, and age.

Head hair grows at an average rate of 1.3 cm/month although there is some variation according to sex, age, and ethnicity.¹⁴ Mangin and Kintz¹⁵ determined morphine and codeine concentrations in human head, axillary, and pubic hair from heroin overdose cases. Morphine concentrations were highest in pubic hair followed by head and axillary hair. Codeine to morphine ratios ranged from 0.054 to 0.273. The slower growth rate of pubic hair and possible drug contribution from sweat or urine were presumed to account for the differences in drug concentration in the different hair samples.

There are multiple possible pathways for drug incorporation into hair, including (1) passive diffusion from blood into the hair follicle; (2) excretion onto the surface of hair from sweat and sebum; (3) passage from skin to hair; and (4) from external contamination. Henderson¹⁶ suggested

Figure 10.6.7 Cocaine (COC) concentrations in plasma and cocaine and benzoylecgonine (BZE) concentrations in human head hair after 150 mg/kg cocaine administration by the subcutaneous route. Data represent the mean average for five subjects. Three separate cocaine administrations occurred on days 0, 2, and 5. The dotted lines for cocaine plasma represent simulated plasma concentrations (not measured). (Data adapted from References 18 and 19.)

that drugs may enter hair from multiple sites, via multiple mechanisms, and at various times during the hair growth cycle. Drugs and their metabolites are distributed throughout the body primarily by passive diffusion from blood. Distribution across membranes is generally facilitated by high lipid solubility, low protein binding, and physicochemical factors that favor the unionized form of the drug in blood. Diffusion of drug from arterial blood capillaries to matrix cells in the base of the follicle is considered a primary means for drug deposition in hair. Presumably, drug binds to components in the matrix and to pigments. As the cells elongate and age, they gradually die and coalesce, forming the nonliving hair fiber. Drug that may be present is embedded in the hair matrix.

Drug entering hair via blood from the capillary plexus of the follicle is not detectable by standard hair cutting methods until hair grows to the skin surface. With daily sampling of beard, the time course for morphine and codeine to appear was reported to be in the range of 7 to 10 days.¹⁷ In controlled dosing studies with cocaine and codeine, these drugs were detectable in “unwashed” human head hair approximately 8 days after the first drug administration.¹⁸ Peak drug concentrations occurred in approximately 15 days. BZE concentrations were detectable over the same time course at approximately one tenth the concentration of cocaine. Figure 10.6.7 illustrates mean concentrations of cocaine in plasma and cocaine and BZE in hair.^{18,19} Of special interest in these studies was the finding that solvent washes removed 50 to 55% of cocaine and codeine in the first hair specimens collected after drug dosing, but minimal drug was removed by solvent washing of specimens collected in later weeks. It was concluded that early deposition of drug on hair by sweat accounted for the differences observed in solvent washing and that multiple mechanisms may be involved in drug deposition in hair. Environmental contamination also has been reported to a potential route of cocaine entry into hair.^{20,21}

10.6.4 Pharmacokinetic, Chemical, and Analytical Considerations

The pattern of disposition of drugs in alternative matrices is influenced by time of collection relative to dosing, frequency of drug use, chemical and physiological differences between alternative matrices, and chemical differences between drugs and between parent drug and metabolites. The relative abundance of parent drug and metabolites is a dynamic process, especially over the first

12 to 24 h after drug administration. Generally, parent drug concentrations are highest in biological tissues during this time. Some drugs, such as heroin, may be metabolized so quickly that their presence in tissues like blood and urine may be extremely short-lived. In contrast, heroin sequestration in hair and in sweat (sweat patch) may have a stabilizing effect and preserve the molecule intact for detection for long intervals after use. Metabolic processes and distribution to tissues proceeds rapidly, thereby altering relative abundances of parent drug and metabolites. Multiple dosing also can exert significant influences on the pattern of drug disposition. Frequently, drug metabolites have a longer half-life than the parent, resulting in accumulation of metabolites to concentrations exceeding those of the parent drug. In some cases, metabolites are the only detectable analytes. Table 10.6.1 presents a summary of metabolic and chemical influences on drug and metabolite distribution in alternative matrices.

Development of drug testing methodologies for alternative matrices involves consideration of the spectrum of target analyte(s) and acceptable cutoff concentration(s) for useful detection windows. Table 10.6.2 provides a summary of target analytes, pharmacokinetic considerations, references for analysis of each drug, and for interpretation of results. Each alternative matrix has unique characteristics that influence test outcomes. Some generalities are useful as guides to alternative matrices testing:

Detection methods for drugs in urine:

- Frequently target end-stage metabolites
- Frequently require a hydrolysis step to measure conjugated metabolites
- Demand only moderate to high sensitivity due to the concentrating ability of the kidneys

Detection methods for drugs in oral fluid and blood:

- Have similarities in target analyte distribution and time course of detection, except for cannabis where detection in oral fluid is primarily due to sequestration of THC in the oral cavity
- Frequently measure active parent drug
- Require ultrasensitive methodology due to low concentrations

Detection methods for drugs in sweat and hair:

- Generally have similar distribution of parent drug and metabolites
- Require ultrasensitive methodology due to low concentrations

10.6.5 Interpretation of Alternative Matrices

10.6.5.1 Time Course of Detection in Alternative Matrices

The time course of detection of drugs and metabolites in alternative matrices varies from hours to months depending on the type of biological specimen being tested. Generally, drug detection times follow the following order: blood < oral fluid < urine < sweat < hair. A general scheme for drug detection in different matrices is shown in Figure 10.6.8. Drug detection in blood and oral fluid generally follows the same time course. Drugs of abuse are generally detected in blood and oral fluid from 1 to 3 days depending on the pattern of drug usage and cutoff concentration.

Single doses of most drugs of abuse are detected in urine for 1 to 3 days.²² Multiple dosing extends the detection window for cocaine, opiates, and amphetamines by 1 to 2 days, whereas multiple dosing of cannabis and phencyclidine may result in positive urine test results for up to 27 days.²³ A short lag time (hours) may be observed for drug appearance in urine following drug administration. For example, in some individuals, delays up to 4 h have been noted for the appearance of cannabinoids in urine following marijuana smoking.²⁴

Studies on sweat testing with the Sweat Patch showed that it takes approximately 2 to 8 h following drug administration for sufficient drug to be deposited in the patch for detection. Additional cocaine use, while the patch is being worn, results in further deposition. Cocaine use 24 to

Table 10.6.1 Metabolic and Chemical Influences on Drug and Metabolite Distribution in Alternate Matrices

Drug	Blood	Urine	Oral Fluid	Sweat	Hair
Cannabis	THC highly lipid soluble and rapidly distributed to tissues resulting in a short detection period; THCCOOH formed rapidly from THC; significant accumulation of THCCOOH may occur from frequent use	THCCOOH conjugated and rapidly excreted; accumulation after multiple dosing significantly extends detection period	THC sequestered in oral cavity after smoking and ingestion providing basis for detection; sequestered THC in oral mucosa may influence blood THC	THC found in low concentrations (<2 ng/patch), after controlled drug administration of up to 27 mg; THC in sweat from frequent users can be >100 ng/patch or Drugwipe	THC and THCCOOH sequestered in hair matrix; identification of THCCOOH considered evidence of active use; THCCOOH present in extremely low concentrations
Cocaine	COC rapidly converted to BZE and EME; hydrolysis to BZE continues to occur after collection unless chemically stabilized	COC and BZE rapidly excreted; rate of COC excretion may be influenced by urine pH; BZE has longer half-life	Acidic pH of oral fluid concentrates COC compared to blood; acidic pH enhances stability of COC; BZE concentration < blood	Acidic pH of sweat enhances stability of COC, but hydrolysis to BZE in collection device may occur	Cocaine binding to hair matrix enhances stability; hydrolysis to BZE may occur; BZE/COC ratio >0.1, cocaine/ethylene or norcocaine considered evidence of active use
Heroin/morphine	HER rapidly hydrolyzed to 6-AM and MOR; lipid solubility of heroin and 6-AM facilitates rapid uptake into tissues as compared to morphine; MOR extensively conjugated	MOR and conjugated MOR rapidly excreted; 6-AM excreted in small amounts for a few hours after heroin administration	Acidic pH of oral fluid enhances 6-AM concentration compared to blood; pH enhances stability of 6-AM	Acidic pH of sweat enhances stability of heroin and 6-AM, but hydrolysis to MOR in collection device may occur	HER and 6-AM binding to hair matrix enhances stability; hydrolysis to MOR may occur
Codeine	COD rapidly and extensively metabolized by conjugation; forms small amounts of active metabolite (MOR) considered responsible for effects; genetic variability in O-demethylation activity	COD, conjugated COD, MOR and conjugated MOR rapidly excreted	Acidic pH of oral fluid enhances COD concentration compared to blood	Acidic pH of sweat likely enhances COD concentration	COD bound to hair matrix; no further metabolic changes considered likely to occur
PCP	PCP highly lipid soluble and rapidly distributed to tissues	Rate of excretion influenced by urine pH	Acidic pH of oral fluid likely enhances concentration compared to blood	Acidic pH of sweat likely enhances concentration	PCP bound to hair matrix; no further metabolic changes considered likely to occur
Amphetamine	AMP lipid soluble and rapidly distributed to tissues	Rate of excretion influenced by urine pH	Acidic pH of oral fluid enhances concentration	Acidic pH of sweat likely enhances concentration	AMP bound to hair matrix; no further metabolic changes considered likely to occur
Methamphetamine	METH lipid soluble and rapidly distributed to tissues; limited metabolism to AMP	Rate of excretion influenced by urine pH; presence of AMP generally required for confirmation	Acidic pH of oral fluid enhances concentration	Acidic pH of sweat enhances concentration	METH bound to hair matrix; no further metabolic changes considered likely to occur

Abbreviations: THC = tetrahydrocannabinol; THCCOOH = 11-nor-9-carboxy- Δ^9 -tetrahydrocannabinol; COC = cocaine; BZE = benzoylecgonine; EME = ecgonine methyl ester; HER = heroin; 6-AM = 6-acetylmorphine; MOR = morphine; COD = codeine; PCP = phencyclidine; METH = methamphetamine; AMP = amphetamine.

Table 10.6.2 Relative Abundances of Target Analytes in Alternative Matrices, Pharmacokinetic Considerations, and Selected References to Aid Interpretation of Results

Drug	Blood/Plasma/Serum	Urine	Oral Fluid	Sweat	Hair
Cannabis Target analytes PK effects	THCCOOH > THC Collection time, multiple dosing and long $t_{1/2}$ of THCCOOH alters THCCOOH/THC ratio ^{44–50}	THCCOOH-G > THCCOOH Multiple dosing and long $t_{1/2}$ of THCCOOH produces accumulation and prolonged detection ^{23,51–58}	THC Multiple dosing may produce accumulation and prolonged detection ^{35,69–73}	THC Multiple dosing may produce accumulation and prolonged detection ^{71,74–78}	THC > THCCOOH Multiple dosing may be necessary for detection; metabolite identification important to eliminate environmental contamination ^{79–86}
	BZE > COC > EME > NCOC; CE (with ethanol) Collection time, multiple dosing and long $t_{1/2}$ of BZE alters BZE/COC ratio; COC in combination with ethanol forms CE ^{3,19,87–104}	BZE > COC Collection time, multiple dosing and long $t_{1/2}$ of BZE alters COC/BZE ratio; COC in combination with ethanol forms CE ^{25,60,87,89–91,93–95,105–117}	BZE > COC Collection time, multiple dosing and long $t_{1/2}$ of BZE alters COC/BZE ratio; COC in combination with ethanol forms CE ^{92,94–96,105,118–124}	COC > BZE Collection time, multiple dosing and long $t_{1/2}$ of BZE alters COC/BZE ratio; COC in combination with ethanol forms CE ^{25,32,76,125,126}	COC > BZE > NCOC; CE (with ethanol) Metabolite identification, e.g., NCOC, important to eliminate environmental contamination; presence of CE indicates systemic COC and ethanol exposure ^{18,83,87,97,118,127–140}
Heroin/morphine Target analytes	MOR-G > MOR > 6-AM > HER Collection time, multiple dosing and long $t_{1/2}$ of MOR alters MOR-G/MOR/6-AM ratios; HER and 6-AM frequently not detected ^{17,96,97,141–148}	MOR-G > MOR > 6-AM > HER Collection time, multiple dosing and long $t_{1/2}$ of MOR alters MOR-G/MOR/6-AM ratios; HER and 6-AM frequently not detected ^{17,87,143,144,149–163}	6-AM MOR > HER 6-AM and MOR most frequently detected; HER may also be detected ^{17,75,87,96,141,142,150,159,164–166}	6-AM MOR > HER 6-AM and MOR most frequently detected; HER also may be detected ^{74–76,125,126,163,167–169}	6-AM > MOR Multiple dosing may be necessary for detection; 6-AM and MOR most frequently detected, but HER also may be detected ^{77,83,87,97,127,128,130–135,139,142,143,165,170–174}
Codeine Target analytes PK effects	COD-G > COD > MOR > NCOD Collection time, multiple dosing may alter COD-G/COD/MOR/NCOD ratios ^{17,19,142,175–178}	COD-G > COD > MOR > NCOD Collection time, multiple dosing may alter COD-G/COD/MOR/NCOD ratios; MOR may exceed COD late in excretion phase ^{17,149,160,179–184}	COD > MOR Collection time, multiple dosing may alter COD/MOR ratio; MOR may not be detected ^{17,123,142,166,175,177,178,185–188}	COD > MOR Collection time, multiple dosing may alter COD/MOR ratio ^{32,123,189,190}	COD > MOR > NCOD Multiple dosing may be necessary for detection ^{17,18,127,142,191–197}

Continued

Table 10.6.2 Relative Abundances of Target Analytes in Alternative Matrices, Pharmacokinetic Considerations, and Selected References to Aid Interpretation of Results (Continued)

Drug	Blood/Plasma/Serum	Urine	Oral Fluid	Sweat	Hair
PCP Target analytes PK effects	PCP Multiple dosing may substantially increase detection time ⁹⁸⁻²⁰⁷	PCP > HO-PCP Multiple dosing may substantially increase detection time ^{202,208-211}	PCP Multiple dosing may substantially increase detection time ^{212,213}	PCP Multiple dosing may substantially increase detection time ⁷⁶	PCP Multiple dosing may be necessary for detection ^{136,214-219}
	AMP Multiple dosing may increase detection time ^{204,220-224}	AMP Multiple dosing may increase detection time ^{221,225-242}	AMP Multiple dosing may increase detection time ^{35,36,75,223,224,241,243,244}	AMP Multiple dosing may increase detection time ^{35,75,243,245}	AMP Multiple dosing may be necessary for detection ^{36,38,82,97,128,131,222,243,246-255}
Methamphetamine Target analytes PK effects	METH > AMP Multiple dosing may increase detection time ^{204,220,221,243,256-260}	METH > AMP Collection time, multiple dosing may alter METH/AMP ratio ^{221,226,229,231-233,235,237,241-243,258,261-268}	METH > AMP Collection time, multiple dosing may alter METH/AMP ratio ^{241,243,244,269}	METH > AMP Collection time, multiple dosing may alter METH/AMP ratio ^{243,269,270}	METH > AMP Multiple dosing may be necessary for detection; AMP present in lower amounts ^{243,248,249,251-255,269,271-275}
MDA/MDMA/MDEA Target analytes PK effects	MDMA demonstrates nonlinear rise in plasma levels with increasing dose; poor CYP2D6 metabolizers may be at risk of toxicity ²⁷⁶⁻²⁸¹	Rapidly excreted primarily as parent drug, <i>N</i> -desmethyl-metabolites, and hydroxyl-metabolites ^{233,279-285}	Acidic pH of oral fluid enhances concentration compared to blood ^{277,281}	Detectable in sweat for 2-12 h after administration ^{286,287}	MDA/MDMA/ MDEA/MDMA concentrations usually exceed MDA (metabolite) ^{135,219,247-249,251-253,288-292}

Abbreviations: THC = tetrahydrocannabinol; THCCOOH = 11-nor-9-carboxy- Δ^9 -tetrahydrocannabinol; THCCOOH-G = 11-nor-9-carboxy- Δ^9 -tetrahydrocannabinol-glucuronide; COC = cocaine; BZE = benzoyllecgonine; EME = ecgonine methyl ester; NCOC = norcocaine; CE = cocaethylene; MOR-G = morphine glucuronide; MOR = morphine; HER = heroin; 6-AM = 6-acetylmorphine; COD-G = codeine glucuronide; COD = codeine; PCP = phencyclidine; HO-PCP = hydroxyphencyclidine; METH = methamphetamine; AMP = amphetamine; MDA = methylenedioxymethamphetamine; MDMA = methylenedioxymethamphetamine; MDEA = methylenedioxyethylamphetamine.

Figure 10.6.8 General detection times for drugs in blood, oral fluid, urine, sweat, and hair. Lighter shaded area of sweat indicates possible detection of drug use that occurred 24–48 h prior to application of sweat patch.

48 h prior to application of the patch may also produce positive results.²⁵ However, drug use just prior to patch removal is not likely to be detected because of the delay in appearance of drug in sweat.

Multiple mechanisms for drug entry into hair may account for the confusion regarding the beginning of the drug detection window.^{18,26,27} Drug excreted in sweat may appear on hair within hours after use, but also may be more difficult to detect if washing procedures efficiently remove the bulk of drug residue. A period of hair growth estimated to be 3 to 5 days¹⁴ must occur for drug in hair to appear at the skin surface, thereby accounting for the “lag” period (days) in its detection window.

Changes in analytical sensitivity and specificity, e.g., antibody changes in the screening assay, may result in enhanced or diminished detection times for all types of specimens. Also, administrative changes in recommended cutoff concentrations could have a similar effect.

10.6.5.2 Multiple Specimen Testing

Continued development, approval, and use of alternative matrices in drug testing programs may present interesting problems in interpretation of results. In the past, it was rare to have test results from more than one type of specimen, particularly in workplace testing. The financial costs of testing more than one type of biological specimen almost certainly will force most drug testing programs to choose a single type of specimen best suited to their needs; however, there are likely to be instances when individuals and even entire drug testing programs decide to test more than one biological specimen. Already, individuals informed of positive test results may request additional testing; e.g., an individual who tested positive in a urine testing program may choose to undergo hair testing. Medical Review Officers may also request additional testing if there is reasonable doubt concerning the validity of a test result. Post-accident testing calls for the highest scrutiny regarding the potential role of drugs as causative factors; hence, multiple specimens may become the norm in this type of testing arena. In addition, drug testing authorities may want information on test comparability, e.g., urine vs. oral fluid testing, prior to switching to a new matrix. Consequently, it is quite likely that there will be many instances where multiple test results from different biological matrices will be collected and require interpretation.

10.6.5.3 Guidance in Interpretation of Alternative Matrices Results

Considerable guidance information is available for interpretation of positive urine test results.^{22,28} Although there is less information available for alternative matrices, a number of reviews

are helpful in this regard.^{1,2,4,29-43} When multiple test results from different matrices are available, interpretation may be considerably more complex, particularly for disparate results. There are a number of legitimate reasons why one might obtain disparate results. Each type of biological specimen has unique physiological and chemical properties that may alter the pattern of drug disposition. For example, renal excretion processes favor elimination of water soluble metabolites, whereas excretion of drug into oral fluid favors parent drugs capable of rapid passive diffusion across membranes. Sweat excretion processes also appear to favor parent drug. The acidic nature of oral fluid and sweat favors excretion and trapping of drugs containing basic nitrogen moieties. Although the complex mechanisms for drug binding to hair pigment and proteins have not been fully elucidated, it is clear that these binding processes exhibit greater affinity for drugs containing basic nitrogen moieties. Residence times in each matrix also differ substantially, yielding wide variability in windows of detection.

The many differences in physiological and chemical properties of alternative matrices undoubtedly result in production of occasional disparate test results when more than one type of biological specimen is utilized for testing. There are many possible explanations for disparate results. For example, testing two different matrices, e.g., urine and oral fluid, may result in two equivalent or two disparate results. When one considers the possible combinations of results that could arise from testing of blood, urine, oral fluid, sweat, and hair, there are 20 possible disparate results if only two matrices are tested. The different scenarios of disparate results for two specimens and some of the possible explanations are depicted in Table 10.6.3. It will become the responsibility of the Medical Review Officer and forensic toxicologists to provide interpretation of such results. Clearly, much information must be available to provide a scientific basis for the interpretation of alternative matrices' results.

Table 10.6.3 Disparate Results from Testing Two Different Biological Matrices and Possible Explanations

Scenario	Matrix					Possible Explanations for Disparate Results
	Blood	Urine	Oral Fluid	Sweat	Hair	
1	Positive	Negative				Time of urine collection too close to time of drug use
2	Positive		Negative			Highly protein-bound drugs may be poorly distributed to oral fluid, e.g., benzodiazepines
3	Positive			Negative		Low drug dose; sampling time outside detection "window"
4	Positive				Negative	Low drug dose; low binding affinity to hair matrix; hair treatments, e.g., bleaching, straighteners; sampling time outside detection "window"
5	Negative	Positive				Long interval after dosing; concentration effect by kidney
6		Positive	Negative			Long interval after dosing; concentration effect by kidney; highly protein-bound drug; sampling time outside detection "window"
7		Positive		Negative		Concentration effect by kidney; sampling time outside detection "window"
8		Positive			Negative	Concentration effect by kidney; low dose; low binding affinity to hair matrix; sampling time outside detection "window"
9	Negative		Positive			Insufficient time for drug absorption; "depot" effect
10		Negative	Positive			Insufficient time for drug absorption, metabolism and excretion; "depot" effect
11			Positive	Negative		Insufficient time for drug absorption, metabolism and excretion; "depot" effect; sampling time outside detection "window"
12			Positive		Negative	Low drug dose; low binding affinity to hair matrix; insufficient time for drug absorption, metabolism and excretion; sampling time outside detection "window"
13	Negative			Positive		Sampling time outside detection "window"
14		Negative		Positive		Sampling time outside detection "window"
15			Negative	Positive		Sampling time outside detection "window"
16				Positive	Negative	Low drug dose; low binding affinity to hair matrix; insufficient time for drug absorption, metabolism and excretion; sampling time outside detection "window"
17	Negative				Positive	Sampling time outside detection "window"
18		Negative			Positive	Sampling time outside detection "window"
19			Negative		Positive	Sampling time outside detection "window"
20				Negative	Positive	Sampling time outside detection "window"

10.7 SPECIMEN VALIDITY TESTING

Yale H. Caplan, Ph.D., DABFT

National Scientific Services, Baltimore, Maryland

Urine drug testing is, by its nature and the privacy considerations, decisions, and laws of the federal government and the states, an unobserved process. This is the standard practice unless there is specific individual suspicion that a specimen has been altered or substituted. Although the practice of tampering had been reported prior to the implementation of the federally regulated workplace drug-testing program, the problem became evident in the 1990s with the introduction of “Urine Aid” and later “Klear,” products among others advertised to “Beat a Drug Test.” Earlier methods were crude and often ineffective utilizing more commonly available products such as salt, bleach, soap, and vinegar and sharing information about such products by “word of mouth.” Later a

significant cottage industry grew through health food stores, advertisements in *High Times* and other magazines and extensive citation on the Internet.

How effective can a drug-testing program be if a magic potion priced at \$20 to \$30 can provide a person a means to evade detection? In a deterrent-based program, credibility can rapidly decline if users believe they can beat the test. The Department of Health and Human Services (HHS) and the Department of Transportation (DOT) developed countermeasures by causing laboratories to inspect and test specimens, verify their normal composition, and search for foreign chemicals. The term *specimen validity testing* (SVT) was coined to identify a sequence of testing designed to check if urine was really urine and if the urine was normal or adulterated. This task was not so simple. Laboratories developed credible tests for the five classes of drugs, substances of known composition and predictable outcome, and were now faced with developing tests for a variety of specimen characteristics and an array of unknown compounds. Indeed, the task of comprehensively searching for normal elements that comprise urine and ascertaining that no foreign materials have been added can be more complex and costly than the drug testing itself.

The intent of the donor is to subvert the drug testing procedure and create a false negative result. This can be accomplished in three ways: (1) by diluting the urine through excessive fluid intake, (2) by substituting other urine, hopefully drug free urine, in place of the donor's urine, and (3) adulterating the urine by adding a chemical to the specimen that either destroys the drug in the urine or otherwise interferes with the laboratory immunoassay tests.

10.7.1 Characteristics of Urine

Urine is an aqueous solution produced by the kidneys. A review of urine characterization with emphasis on workplace testing has been compiled.¹ Urine's major constituents are primarily electrolytes, metabolic excretory products, and other substances eliminated through the kidneys. The initial characterization of a urine specimen is based on its appearance. Color, clarity, odor, and foaming properties contribute to the appearance of urine.

The color of a urine specimen is related to the concentration of its various constituents, most notably urochromes, which exhibit yellow, brown, and red pigments. A normal first morning void has a distinct deep yellow color. It should not be colorless. The characteristic yellow color is predominately caused by the presence of urobilinogen, a hemoglobin breakdown product. After hydration, urine is usually straw-colored, indicating dilute urine. Very dilute urine is essentially colorless and has a water-like appearance.

A normal fresh void is clear and transparent. Freshly voided urine that is cloudy or turbid can indicate the presence of white blood cells, red blood cells, epithelial cells, or bacteria. Upon standing, flaky precipitates from urinary tract mucin may appear in the specimen. Aged alkaline urine may become cloudy because of crystal precipitation. After a lipid-rich meal, urine may also become alkaline and cloudy.

Freshly voided urine is normally odorless. With age, urine acquires a characteristic aromatic odor. As the constituents in the urine decompose, ammonia, putrefaction compounds, and hydrogen sulfide are detected. Certain foodstuffs, such as coffee, garlic, or asparagus, give a distinctive scent. Patients with poorly controlled diabetes produce ketone bodies such as acetone, which impart a fruity odor to urine.

Urine foaming is caused by the presence of protein in the specimen, and foam bubbles should not exhibit the rainbow appearance that is indicative of soap contamination.

10.7.2 Chemical Constituents and Other Characteristics of Urine

The kidneys filter plasma, reabsorb most of the dissolved substances that are filtered, secrete some of these substances back into its filtrate, and leave behind a concentrated solution of metabolic waste known as urine. Metabolic waste products are present in urine at high concentrations.

Creatinine is spontaneously and irreversibly formed from creatine and creatine phosphate in muscle. Creatinine, creatine's anhydride, is a metabolic waste product that is not reutilized by the body. Because there is a direct relationship between creatinine formation and muscle mass, creatinine production is considered constant from day-to-day provided that muscle mass remains unchanged. In view of this constant production, random creatinine results approximate 24-h collection reference intervals. Creatinine is freely filtered by the renal glomeruli and is not significantly reabsorbed by the renal tubules, but a small amount is excreted by active renal tubular secretion. Creatinine is excreted at a relatively constant rate relatively independent of diuresis, provided kidney function is not impaired. Creatinine production and excretion are age and sex dependent. Normal urine creatinine concentrations are greater than 20 mg/dl. Abnormal levels of creatinine may result from excessive fluid intake, glomerulonephritis, pyelonephritis, reduced renal blood flow, renal failure, myasthenia gravis, or a high meat diet.

Specific gravity assesses urine concentration, or amount of dissolved substances present in a solution. As increasing amounts of substances are added to urine, the concentration of these dissolved substances and the density, or the weight of the dissolved substances per unit volume of liquid, increase. Specific gravity varies greatly with fluid intake and state of hydration. Normal values for the specific gravity of human urine range from approximately 1.0020 to 1.0200. Decreased urine specific gravity values may indicate excessive fluid intake, renal failure, glomerulonephritis, pyelonephritis, or diabetes insipidus. Increased urine specific gravity values may result from dehydration, diarrhea, excessive sweating, glucosuria, heart failure, proteinuria, renal arterial stenosis, vomiting, and water restriction.

pH is the inverse logarithmic function of the hydrogen ion concentration. It serves as an indicator of the acidity of a solution. The two organs that are primarily responsible for regulating the extremely narrow blood pH range that is compatible with human life are the lungs and the kidneys. The kidneys maintain the blood pH range by eliminating metabolic waste products. The pH of the urine is used clinically to assess the ability of the kidneys to eliminate toxic substances. Urinary pH undergoes physiological fluctuations throughout the day. Urinary pH values are decreased in the early morning followed by an increase in the late morning and early afternoon. In the bacteria-contaminated urine specimen, pH will increase upon standing because of bacterial ammonia formation. Normal urinary pH values range from 4.5 to 9.0.

10.7.3 The Role of HHS and DOT in Specimen Validity Testing

HHS through its Mandatory Guidelines for Federal Workplace Drug Testing and other notices has directed laboratories in the conduct of specimen validity tests. The early guidelines permitted testing but did not define the characteristics. When the adulteration and substitution issues became more prominent, HHS and DOT issued guidance. These were considered voluntary.

HHS–SAMHSA Program Document (PD) 33

Title: Testing Split (Bottle B) Specimen for Adulterants

Dated: March 9, 1998

Summary: The guidance established technical threshold “cutoff” values for pH and nitrates. It required laboratory testing for pH and nitrite concentration in any split specimen that failed to reconfirm. It also authorized additional adulteration testing for the presence of glutaraldehyde, surfactants, bleach, and other adulterants if indicated.

HHS–SAMHSA Program Document (PD) 35

Title: Guidelines for Reporting Specimen Validity Test Results

Dated: September 28, 1998

Summary: PD 35 replaced the Category I, II, and III reporting protocols established in 1993 with more detailed laboratory test reporting protocols. It established unacceptable limits for nitrite concentration, pH, and substitution. It required further testing when a split specimen failed to reconfirm.

U.S. DOT–Office of Drug and Alcohol Policy and Compliance (ODAPC)

Title: MRO Guidance for Interpreting Specimen Validity Test Results

Dated: September 28, 1998

Summary: This companion document to PD 35 contained formal regulatory guidance for MROs, detailing how they were to respond to the various laboratory reporting protocols.

HHS–SAMHSA Program Document (PD) 37

Title: Specimen Validity Testing

Dated: July 28, 1999

Summary: PD 37 provided specific technical guidelines to the laboratories. The document notes that specimen validity testing *may* be conducted on Bottle A and *must* be conducted on Bottle B if Bottle B fails to reconfirm for the requested drug/analyte. Specimen validity tests *may* include, but are not limited to, tests for creatinine concentration, specific gravity, pH, nitrite concentration, pyridine, glutaraldehyde, bleach, and soap. These tests must be performed using methods that are validated by the laboratory.

Subsequently, DOT published its final rule, 49CFR Part 40, on December 19, 2000² and a technical amendment to the Final Rule on August 1, 2001.³ The 2000 rule mandated validity testing but the 2001 amendment changed this to *authorized* but *not mandated* pending future HHS actions. The rule section 40.91 states:

What validity tests must laboratories conduct on primary specimens?

Creatinine and specific gravity (SG)

SG if Creatinine < 20 mg/dl

Measure pH

Substances that may be used to adulterate urine

Send to second laboratory if unable to confirm adulterant

New adulterant, report to DOT and HHS

Complete testing for drugs

Conserve specimen

Most recently HHS published its Revised Mandatory Guidelines for Workplace Drug Testing Programs on April 13, 2004 with an effective date of November 1, 2004.⁴ It defined the final SVT requirements. Notably it included the following:

1. Creatinine concentration criterion defining a substituted specimen changed to <2 mg/dl
2. SG analysis with four decimal places required to report as substituted or as invalid based on creatinine and SG
3. Added definitions specifically associated with SVT
 - Initial drug test, initial validity test
 - Confirmatory drug test, confirmatory validity test
 - Dilute specimen, adulterated specimen
 - Donor empties pockets and displays for collector
4. Included all the reporting requirements to report a specimen adulterated, substituted, diluted, or as an invalid result
5. Added a requirement to report the actual numerical values (concentrations) for adulterated results, and the confirmatory creatinine concentration and confirmatory SG result for a substituted specimen
6. Added specimen retention requirements for the laboratory
7. Provided a list of fatal flaws and correctable flaws
8. Expanded retest requirements for drugs
9. Mandated agencies to have BQC that are adulterated or substituted
10. MRO review expanded to include adulterated and substituted specimens and reporting
11. Requires laboratories to conduct drug and validity testing at the same facility
12. Defined requirements for creatinine and SG:
 - Determine the creatinine on every specimen

- Determine the SG if creatinine < 20 mg/dl
 - Determine SG to four decimal places if reporting a specimen as substituted or as invalid based on creatinine and SG
13. Determine the pH on every specimen
 14. Perform one or more validity tests for oxidizing adulterants on every specimen
 15. Perform additional validity tests when the following conditions are observed:
 - Abnormal physical characteristics
 - Reactions or responses characteristic of an adulterant during testing
 - Possible unidentified interfering substance or adulterant
 16. May send to second laboratory if unable to confirm adulterant (laboratory and MRO decide)
 17. If a new adulterant is identified, report to DOT and HHS
 - Complete testing for drugs
 18. Conserve specimen

According to these guidelines:

Substituted is a specimen with

- Creatinine < 2 mg/dl and SG < 1.0010 or
- Creatinine < 2 mg/dl and SG > 1.0200

Dilute is a specimen with

- Creatinine 2 to <20 mg/dl and
- SG 1.0010 to 1.0030

Invalid is a specimen in which inconsistent creatinine concentration and SG results are obtained, i.e.,

- Creatinine less than 2 mg/dl on *both* the initial and confirmatory creatinine tests and SG greater than 1.0010 but less than 1.0200 on *either or both* the initial and confirmatory SG tests
- Creatinine greater than or equal to 2 mg/dl on *either or both* the initial or confirmatory creatinine tests and SG less than or equal to 1.0010 on both the initial and confirmatory SG tests

A urine specimen is reported adulterated when:

- pH < 3
- pH ≥ 11
- Nitrite concentration ≥ 500 µg/ml (two different tests required)
- Chromium (VI) concentration ≥ 50 µg/ml (two different tests required)
- Halogen is detected and confirmed, with a specific concentration ≥ the LOD of the confirmatory test on the second aliquot (two different tests required)
- Glutaraldehyde is detected and confirmed, with a concentration ≥ the LOD of the confirmatory test on the second aliquot (two different tests required)
- Pyridine is detected and confirmed, with a concentration ≥ the LOD of the confirmatory test on the second aliquot (two tests required)
- Surfactant is detected and confirmed, with a ≥100 µg/ml dodecylbenzene sulfonate-equivalent cutoff concentration on the second aliquot (two tests required)
- The presence of any other adulterant not specified is verified using an initial test on the first aliquot and a different confirmatory test on the second aliquot

The reporting requirements are summarized in Table 10.7.1. The table was provided by HHS as part of the Mandatory Guidelines effective November 1, 2004. It describes the conditions for positive and negative drug test results as well as adulterated and substituted SVT results; however, it expands the number of conditions for which a specimen is reported as invalid. The increased number of SVT tests plus many more tests that cannot be satisfactorily completed caused a significant increase in the number of invalid reports.

10.7.4 Role of the Medical Review Officer

Medical Review Officers are required to review tests reported as adulterated, substituted, and invalid. Although the HHS Mandatory Guidelines are in effect, there exist some differences between

Table 10.7.1 HHS Reporting Template

Effective 11-1-2004

Result Box(es) checked on Federal CCF (Step 5a) or Result indicated on Electronic Report	Note
Negative	All drug tests are negative and all specimen validity test results are acceptable
Negative and Dilute	For DOT-regulated specimens: provide Creatinine & SpGr numerical values (See Below)
Invalid Result	State reason for invalid result (See Below)
Positive, Specific Drug	No comment required
Positive, Specific Drug, and Dilute	No comment required
Positive, Specific Drug, and Adulterated	State reason for adulterated result (See Below)
Positive, Specific Drug, and Substituted	Provide Creatinine & SpGr numerical values (See Below)
Positive, Specific Drug, and Invalid Result	State reason for invalid result (See Below)
Adulterated	State reason for adulterated result (See Below)
Adulterated and Invalid Result	State reasons for adulterated & invalid results (See Below)
Adulterated and Substituted	State reason for adulterated result & provide Creatinine and SpGr numerical values (See Below)
Substituted	Provide Creatinine and SpGr numerical values (See Below)
Substituted and Invalid Result	Provide Creatinine and SpGr numerical values & state reason for invalid result (See Below)
Rejected for Testing	State reason for rejecting specimen (See Below)

Test Result	Specific Comment Required on Remarks Line (Step 5a) of the CCF and on Electronic Report	Note
Negative and Dilute	For DOT-Regulated specimens: Creatinine = (numerical value) mg/dL & SpGr = (numerical value)	
Substituted	Creatinine = (conf. test numerical value) mg/dL & SpGr = (conf. test numerical value)	
Adulterated	pH = (conf. test numerical value)	
	Nitrite = (conf. test numerical value) mcg/mL	
	Chromium (VI) = (conf. test numerical value) mcg/mL	
	(Specify Halogen) Present	
	Glutaraldehyde = (conf. test numerical value) mcg/mL	
	Pyridine = (conf. test numerical value) mcg/mL	
	Surfactant Present (Specify Adulterant) Present	
Invalid Result	Creatinine < 2 mg/dL; SpGr Acceptable	SpGr >1.0010 & <1.0200
	SpGr ≤ 1.0010; Creatinine ≥ 2 mg/dL	
	Abnormal pH	
	Possible (Characterize as Oxidant, Halogen, Aldehyde, or Surfactant) Activity*	
	Immunoassay Interference*	
	GC/MS interference*	
	Abnormal Physical Characteristic - (Specify)*	
Rejected for Testing	Bottle A and Bottle B - Different Physical Appearance*	
	Fatal Flaw: Specimen ID number mismatch/missing	
	Fatal Flaw: No collector printed name & No signature	
	Fatal Flaw: Tamper-evident seal broken	If redesignation is not possible
	Fatal Flaw: Insufficient specimen volume	
	Uncorrected Flaw: Wrong CCF Used	Wait 5 business days before reporting flaw if uncorrected
	Uncorrected Flaw: Collector signature not recovered	

* Lab shall contact the MRO to discuss the Invalid Result

Revised January 4, 2005

DOT and HHS requirements. First HHS mandates SVT for the federal agencies it controls. DOT incorporates HHS requirements in its rules but at present they are not entirely compatible. DOT SVT testing is authorized but not mandated. In addition, DOT published an interim final rule on May 28, 2003,⁵ changing the creatinine criterion to <2 from 5 mg/dl and an additional interim rule on November 9, 2004⁶ to incorporate most of the HHS rule. The differences are as follows:

- HHS — Laboratories report quantitative creatinine and SG values for adulterated and substituted only
- DOT — Laboratories report quantitative creatinine and SG values for all negative dilute specimens

MROs are required to take the following actions if the creatinine is above 2 mg/dl:

- HHS — No requirements
- DOT — Creatinine 2 or greater but less than 5 mg/dl with appropriate SG: Recollect under direct observation
- DOT — Creatinine 5 or greater but less than 20 mg/dl with appropriate SG: If negative (drug) may, but not required, to take another test immediately

10.7.5 Dilution/Substitution

A donor may attempt to decrease the concentration of drugs or drug metabolites that may be present in his or her urine by dilution. Deliberate dilution may occur *in vivo* by consuming large volumes of liquid or *in vitro* by adding water or another liquid to the specimen. Donors also have been known to substitute urine specimens with drug-free urine or other liquid during specimen collection. Due to donor privacy considerations, collections for federally regulated drug testing programs are routinely unobserved. Therefore, dilution and substitution may go undetected by collectors and thus provide a viable method for donors to defeat drug tests. There are many products available today purporting to “cleanse” the urine prior to a drug test; some of which are diuretics. Others are designed specifically for urine specimen substitution, including drug-free urine, additives, and containers/devices to aid concealment. Some devices have heating mechanisms to bring the substituted specimen’s temperature within the range set by HHS to determine specimen validity at the time of collection (i.e., 32 to 38°C/90 to 100°F). Additional products include prosthetic devices to deceive the collector/observer even during a direct observed collection.

According to federal guidelines, a specimen is:

Dilute if the creatinine is < 20 mg/dl and the specific gravity is < 1.003 , unless the criteria for a substituted specimen are met.

The concentration of drug metabolites in urine is a function of collection time (related to drug use) and relative water content. The goal of the suborner is to dilute the urine and the drugs in it to concentrations that are below the cutoff concentrations for the various drugs. Hydration simply reduces the detection time since last use. It may or may not be significant. Attempts to manage intentional hydration are limited by the fact that normal hydration and specific gravity are highly variable. One cannot unduly restrict water consumption on one hand, and demand an adequate volume of urine from a donor on the other.

There are currently no effective techniques to address the issue of dilution. Most dilute specimens probably occur as the result of hydration — donor drinking large quantities of fluids prior to the collection — rather than the external addition of water to a specimen after it has been provided. Heated water sources should not be available; hence, external hydration should result in detection through temperature checks. Other water sources should be blued with dye to facilitate detection if used.

The most appropriate solution to the dilution problem would be to lower the cutoff values when testing for drugs in dilute specimens. However, this is not allowed in most regulated testing

programs (NRC is the exception). The procedures, although technically possible, are not standardized among laboratories in a manner that would assure appropriate uniformity. Such techniques may be valuable, however, in special circumstances for specific situations, especially in nonregulated testing programs.

Diuretics may have the same effect as hydration or dilution. One common belief is that herbal teas (“Golden Seal” is a common example) will effectively protect an individual from detection. There is some historical truth in this belief. In the days when thin-layer chromatography was used to screen for drugs, some material in the tea acted as a masking agent by blocking the visualization of morphine or other opiates. The belief is reinforced by the fact that pigments in the tea result in a change in urine color to a darker hue. With the current immunoassay techniques, there is no value to the teas except the related diuresis and the increased hydration that results.

10.7.6 The Science Underlying the Substituted Specimen

According to federal guidelines, a specimen is:

Substituted (i.e., the specimen does not exhibit the clinical signs or characteristics associated with normal human urine) if the creatinine concentration is < 2 mg/dl *and* the specific gravity is < 1.0010 or > 1.0200 .

Specimens reported as “substituted” have creatinine and specific gravity values that are so diminished or incongruent that they are not consistent with normal human urine. Since the establishment of the federal guidelines for “substituted” specimen criteria, there have been an increasing number of specimens that have been reported as substituted — even some that had apparently been collected under direct observation. Many of these met the “substituted” criteria by having creatinine concentrations and specific gravity levels that were outside the acceptable range. More specifically these are “water-loaded” or “ultra-dilute” specimens.

What is the clinical basis for concluding that a urine specimen meets the current definition of “substituted”? Such a result is the administrative equivalent of an overt “refusal” to be tested or a “positive” drug test.

10.7.6.1 NLCP: State of the Science — Update 1

In February 2000, a technical review was published under the auspices of HHS/SAMHSA, entitled NLCP: “State of the Science – Update #1, Urine Specimen Validity Testing, Evaluation of the Scientific Data Used to Define a Urine Specimen as Substituted.” Its purpose was to provide an overview of the published scientific literature that HHS used to develop the criteria for defining a specimen as substituted. The report’s conclusion was as follows:

In order for a specimen to be reported as substituted, both creatinine and specific gravity must meet defined criteria; that is, urine creatinine < 5 mg/dl *and* urine specific gravity < 1.001 or > 1.020 . This testing requirement provides both an analytical and physiological safeguard. The review of the scientific literature including random clinical studies, medical conditions resulting in severe overhydration or polyuria, and water loading studies confirms that the urine criteria of creatinine < 5 mg/dl *and* urine specific gravity < 1.001 or > 1.020 represent a specimen condition that is *not* consistent with normal human urine. In the deductive evaluation of 47 studies, no exception to the criteria defining a “substituted” specimen was reported.

However, the review cannot be interpreted as conclusive evidence that it is not possible for anyone to physiologically produce a “substituted” urine, since none of the studies cited was designed to look specifically at the amount of water it takes to produce a substituted specimen. Theoretical physiology suggests a lower value and nephrologists have more recently advised that on a mathe-

mathematical basis individuals with low normal serum creatinine values may produce a urine creatinine value slightly below 5 mg/dl.

Later that same year, DOT performed a water-loading study that asked the question: How much water does it take to produce a substituted specimen? Or: How much water can a person consume and still not have a “substituted” specimen?

10.7.6.2 DOT Water Loading Study

The DOT study,⁷ entitled “Paired Measurements of Creatinine and Specific Gravity after Water Loading,” is more on point. The study used 40 female and 13 male volunteers. The first phase was to simulate the shy bladder procedure. The first morning void was collected; then all volunteers were given 40 oz of fluid and were asked to provide a specimen every hour for the first 3 h and to continue with an additional 40 oz or more over the next 3 h. The volunteers were asked to drink as much as they could. Two participants were unable to consume the minimum amount of fluid intended. On the other hand, 11 participants (5 men and 6 women) consumed more than 1 gal of fluid by the end of their test periods. The bottom line was that none of the 480 specimens were identified as “substituted.” The maximal suppression of creatinine values (which is the critical function value) was seen in an individual who had consumed 1.5 gal of water by the 5-h mark. It was reported that the creatinine value approached but was not below 5 mg/dl. Then, interestingly enough, the individual consumed another liter, and in the final hour had an elevated creatinine. Overall, the data showed that many of the volunteers attained levels of specific gravity below the 1.001 threshold value, but did not attain creatinine levels below 5 mg/dl. It, therefore, appeared that individuals cannot consume enough water to have a “substituted” specimen although it may be theoretically possible to do so. The results suggest that it is not physiologically possible to “unintentionally” drink too much water and be confronted with a “refusal to test–substituted specimen.” In the absence of a related medical condition, unintentional ingestion of water seems to be as unlikely as passive inhalation of drugs. (Can a person unintentionally drink 1 1/2 gal of water?)

10.7.6.3 FAA Workplace Urine Specimen Validity Testing Colloquium

In light of several witnessed and documented cases of individuals demonstrating a creatinine concentration slightly below 5 mg/dl, the FAA sponsored a “Workplace Urine Specimen Validity Testing Colloquium,” February 4–6, 2003. The colloquium was organized in direct response to a Congressional mandate to the FAA to prepare a report on whether there were any particular medical conditions, dietary factors, or individual characteristics that could result in a urine specimen meeting the existing criteria of an adulterated or substituted specimen. Participants included, among others, distinguished toxicologists and specific technical experts from the relevant fields of medicine, science, drug testing, and law. The participants had experience in drug-testing programs, medical, and other related fields. Presentations and discussions centered on the physiological impact of medical issues, working conditions, and dietary habits on validity testing conducted on specimens submitted under the DOT workplace program.

In April 2004, FAA released its report with the following findings and conclusions:

1. Dietary habits, medical issues, and working conditions do not affect the validity of specimens.
2. The validity testing criteria as currently established for adulteration are appropriate.

Only a few substituted specimens are attributed to physiological concentrations of urine creatinine (a compound in urine) below the HHS established value. However, the established value for creatinine is not appropriate for all people.

It made the following recommendations:

1. Substitution: The creatinine level for determining substituted specimens should be lowered to less than 2 mg/dl. This will prevent any individual who can achieve this concentration through normal physiological means from being improperly labeled as providing a substituted urine specimen.
2. Dilution: The current creatinine and specific gravity levels for determining a dilute specimen are adequate. For federally regulated programs, specimens identified as dilute should be tested for drugs at lower cutoff values in order to overcome the efforts of individuals to hide the presence of drugs.
3. Adulteration: The levels established for pH (<3 or >11), chromium VI (cutoff concentration of 20 µg/ml or more) and nitrite (greater than or equal to 500 µg/ml) are satisfactory. However, all laboratory testing for adulterants should include two distinct chemical methods to determine the presence of adulterants in the specimens (i.e., one for initial testing and another to confirm the presence of the adulterant).
4. Role of the Medical Review Officer: Supplement current verification process for assessing individuals' claims that they can produce a specimen meeting the substituted criteria through physiological means. Provide additional guidelines and training for the changes in the verification process.

10.7.7 Adulteration

“Adulterated” is the term used for a specimen that has been altered by the donor in an attempt to defeat the drug test. The donor’s goal in this regard is to affect the ability of the laboratory to properly test the specimen for drugs and/or to destroy any drug or drug metabolite that may be present in the specimen.⁸⁻¹⁰ Many substances can be used to adulterate a urine specimen *in vitro*, including common household products, commercial chemicals, and commercial products developed specifically for drug test specimen adulteration. Adulterants are therefore readily available, may be easily concealed by the donor during the collection procedure, and can be added to a urine specimen without affecting the temperature or physical appearance of the specimen. To identify adulterated specimens, HHS requires certified laboratories to perform a pH test and a test for one or more oxidizing compounds on all regulated specimens. Laboratories are also allowed to test regulated specimens for any other adulterant, providing they use initial and confirmatory tests that meet the validation and quality control requirements specified by the HHS Guidelines.

An adulterant may interfere with a particular test method or analyte, but not affect others. For example, an adulterant may cause a false-negative marijuana (cannabinoids) result using a particular immunoassay reagent, but not affect the test results for other drugs. The same adulterant may not affect the test results obtained using a different immunoassay reagent or method. It is also possible for an adulterant to cause a false-positive drug test result, rather than the intended false negative. The initial drug test required for federal workplace programs (immunoassay) is more sensitive to adulterants than the required confirmatory drug test (gas chromatography/mass spectrometry, GC/MS). Currently, the GC/MS assays for marijuana metabolite (THCA) and opiates appear to be the most affected.

An adulterated specimen is defined in 49CFR Part 40.3 as “A specimen that contains a substance that is not expected to be present in human urine, or contains a substance expected to be present but is at a concentration so high that it is not consistent with human urine.” An adulterated specimen may be reported by the laboratory as having a nitrite concentration that is too high, a pH level that is too high or too low, or identified as having a specific adulterant (such as glutaraldehyde) present.

The reference in the HHS guidelines to a general oxidant test is new. Most adulterants used are oxidizing agents and the early tests for nitrite and chromate were oxidant tests, although specifically named as either nitrite or chromate. Since the general characteristic of the adulterants was that of an oxidant, it is practical to use a comprehensive general test for screening purposes to be followed by specific confirmation tests, rather than do a series of similar and potentially cross-reacting tests to screen for adulterants.

HHS allows certified laboratories to test for any adulterant. It is not possible to provide specific program guidance for all substances that may be used as adulterants; however, HHS has included specific requirements in the Guidelines for pH analysis and for the analysis of some known adulterants that follow:

10.7.7.1 pH

The pH of human urine is usually near neutral (pH 7) although some biomedical conditions affect urine pH. HHS set the program cutoffs for pH based on a physiological range of approximately 4.5 to 9. Specimens with pH results outside this range are reported as invalid. An extremely low pH (i.e., less than 3) or an extremely high pH (i.e., at or above 11) is evidence of an adulterated specimen. Urine specimens that are found to have a pH <3 or >11 can be reported as “Specimen Adulterated: pH is too high (or too low).” The establishment and publication of these threshold limits ends the debate and uncertainty that has surrounded the issue of what is a normal urine pH and what margin of safety should be given to upper and lower levels.

To the average donor who may be contemplating the addition of a chemical substance to his to her urine, acids and bases seem like good choices. Battery acid and Drano have been used and are generally available. Such compounds have a significant impact on the pH of the specimen and include hydrochloric (muriatic) acid used for swimming pools. Commercial adulterants that affect pH include Amber-13 and THC-free. Amber-13 is a sulfur-smelling liquid sold in a glass vial. When 8 ml of Amber-13 is mixed with 50 to 150 ml of water it produces a pH of about 1. Urine will probably buffer this to some degree. THC-Free lists its formulation as water, muriatic acid, potassium chloride, phosphoric acid, and potassium hydrogen phosphate. One vial of THC-Free added to 50 ml of urine will produce a pH of between 1 and 2.

10.7.7.2 Nitrite

Nitrite is an oxidizing agent that has been identified in various commercial adulterant products. Nitrite is produced by reduction of nitrate. Nitrite in high concentrations is toxic to humans, especially infants, causing methemoglobinemia by oxidizing the iron in hemoglobin. Nitrate and to a lesser extent nitrite are present in the environment. Nitrite may be normally present in human urine.

There has been a lot of confusion between nitrites and nitrates. It is important to understand the difference between the two compounds.

Nitrite is NO_2 — Nitrites have a therapeutic use as a vasodilator (oral dose = 30 to 60 mg). Inorganic nitrite can be used in treatment of cyanide poisoning (intravenous dose = 300 to 500 mg). One example of an organic nitrite is nitroglycerin. Nitrite is toxic; after accidental ingestion of nitrite, toxic symptoms include weakness, nausea, numbness, shortness of breath, tachycardia, and cyanosis. One reported case of nitrite overdose resulted in a urine concentration of 340 mg/l.

Nitrate is NO_3 — Nitrates have a widespread use as fertilizers, which can lead to accumulation in food plants and water supplies.

Both nitrites and nitrates are also used as curing agents in processed meats. They may legally be present in these products in the following concentrations: nitrites up to 200 ppm and nitrates up to 500 ppm. Some pathological conditions (infection, inflammation), medical treatments (cancer), and urinary tract infections may result in nitrites in urine.

In whole blood, nitrite is unstable. Whole-blood nitrite is almost completely converted to nitrate within 1 h. The nitrate that is formed is almost completely excreted in the urine. Normal nitrite concentrations in urine are very low and have been demonstrated in a variety of studies to generally be below 100-200 $\mu\text{g/ml}$.

Because low levels of nitrite may be present in human urine, HHS set a cutoff level of 500 $\mu\text{g/ml}$ for adulteration and 200 $\mu\text{g/ml}$ for invalid results. These concentrations are well above levels normally seen in human urine. Therefore, normal exposure does not explain a nitrite-adulterated result.

Drug testing laboratories began to study the effects of nitrite in detail when the product Klear came on the market in 1997. A urine specimen would screen positive and then fail confirmation. It would not just fail in the sense that no drug was identified, but it looked like something was destroying all of the organic compounds in the specimen.

Specimens adulterated with Klear were oxidizing THCA during the extraction process. When aliquots to be tested were acidified, the oxidation process exponentially accelerated. The mass ion peaks on the mass spectral chromatograms were absent. There is no drug and there is no internal standard either. The internal standard is a deuterated version of the drug or metabolite being tested. It is added as a control reference for the analysis and its destruction is diagnostic for an oxidizing adulterant.

Some commercial nitrite adulterants include Klear, Whizzies, and Randy's Klear (I). Klear is a product that comes in a small plastic vial containing 500 to 800 mg of white crystals (potassium nitrite). The cost of two tubes is \$29.95. Whizzies (sodium nitrite) appears to be a knockoff product of Klear. It is sold as white powder contained in two vials each containing about 850 mg of the compound.

10.7.7.3 Chromium

Chromium exists in a number of chemical states. The zero valence state, Cr^0 , is the metallic state. Chromium also exists in nature in a divalent [Cr^{2+} , Cr(II)], trivalent [Cr^{3+} , Cr(III)], and hexavalent [Cr^{6+} , Cr(VI)] state. Understanding the significant differences in the chemistry and toxicology is important in understanding and interpreting adulteration results. The divalent state is very unstable and is rapidly changed to Cr^{3+} . The biologically or toxicologically significant states are the trivalent Cr^{3+} and hexavalent Cr^{6+} states.

Trivalent chromium Cr^{3+} is an essential nutrient in diet. It plays a critical role in maintaining normal glucose tolerance. The trivalent chromium is the species found in the dietary supplement chromium picolinate. It is important to realize that even large doses of chromium picolinate will not produce any hexavalent chromium in the urine. It will, naturally, produce a small amount of trivalent chromium in the urine. A literature review shows levels in the low nanogram range. The highest concentration of trivalent chromium reported was 11 ng/ml. Those individuals took 400 µg/day of chromium picolinate for 3 days.

The hexavalent chromium Cr^{6+} is a strong oxidizing agent. Cr^{6+} is reduced to Cr^{3+} ; however, Cr^{3+} is not converted to Cr^{6+} . Cr^{6+} is used in chrome plating, dyes and pigments, leather tanning, and wood preserving. Hexavalent chromium is present in the environment and is a carcinogen. It is a very toxic and irritating compound. In studies that looked at dietary or environmental exposure to hexavalent chromium, the maximum level reported was 690 ng/ml. In this instance, 10 mg/day of Cr^{6+} (in water) were ingested for 3 days. These levels are in stark contrast to what is seen with adulterated urine.

In summary, concentrations of Cr^{3+} in urine are small — in the nanogram per milliliter range. Concentrations of Cr^{6+} found in adulterated urine specimens are large — in the microgram per milliliter range. In addition, the laboratory adulteration assays are specific for Cr^{6+} and do not include Cr^{3+} . Urine concentrations of hexavalent chromium found in adulterated urine specimens exceed the highest toxic case reported. (The case was suicide by ingestion of chromic acid solution; 3 days after ingestion, urine contained 5.13 µg/ml. Death occurred 1 month later from injury.) The HHS reporting cutoff is 50 µg/ml.

Some chromium containing adulterants include Klear II, LL418, Sweet Pee's Spoiler (pyridium chlorochromate), UrineLuck, and Ultra Kleen (chromate).

Pyridinium chlorochromate is a strong oxidizing agent that has been the agent in some commercial adulterants. This compound is identified by urine drug testing laboratories using a confirmatory test for pyridine. Pyridine at any detectable level in a urine specimen is evidence of adulteration.

10.7.7.4 Hydrogen Peroxide and Peroxidase

The commercial adulterant Stealth comes in a packet that contains two plastic vials. One vial contains a tan solid that does not melt. The other vial contains about 1.7 ml of a clear liquid, with

a measured pH of 4.5. The user is instructed to pour the solid into the collection cup, add urine, then add the liquid “activator.” The tan solid contains a peroxidase, the enzyme that speeds the oxidation process. The liquid contains peroxide. Stealth goes to work quickly and oxidizes the THC metabolites in a matter of hours, then “self-destructs.” Hence, the name Stealth.

10.7.7.5 Halogens

Halogens are the four elements fluorine, chlorine, bromine, and iodine. Halogen compounds have been used as adulterants. The term “halogen” (from the Greek *hals*, “salt,” and *gennan*, “to form or generate”) was given to these elements because they are salt formers. None of the halogens can be found in nature in its elemental form. They are found as salts of the halide ions (F^- , Cl^- , Br^- , and I^-). Fluoride ions are found in minerals. Chloride ions are found in rock salt ($NaCl$), the oceans, and in lakes that have a high salt content. Both bromide and iodide ions are found at low concentrations in the oceans, as well as in brine wells. The assays used by certified laboratories identify halogen compounds that act as oxidants. These do not include the halogen salts that may be present in a urine specimen. The presence of an oxidative halogen in a urine specimen is evidence of adulteration.

Iodine/Iodate is a recent adulterant in the halogen class. Molecular iodine (I_2) is a blue black solid that sublimates. Iodide (I^-) is generally found in the form of potassium or sodium salts (KI , NaI). Iodate (IO_3^-) also appears as potassium or sodium salts (KIO_3 , $NaIO_3$) of iodic acid. Iodate is a strong oxidizing agent and is reduced to iodide. Iodide and iodate are used as food and salt additives, in antiradiation products and in thyroid hormones. Normal concentrations are approximately 600 $\mu g/L$.

10.7.7.6 Glutaraldehyde

Glutaraldehyde is a clear, colorless liquid with a distinctive pungent odor sometimes compared to rotten apples. One of the first effective commercial adulterants, UrinAid, was found to contain glutaraldehyde. Glutaraldehyde is used as a sterilizing agent and disinfectant, leather tanning agent, tissue fixative, embalming fluid, resin or dye intermediate, and cross-linking agent. It is also used in X-ray film processing, in the preparation of dental materials, and surgical grafts. Glutaraldehyde reacts quickly with body tissues and is rapidly excreted. The most common effect of overexposure to glutaraldehyde is irritation of the eyes, nose, throat, and skin. It can also cause asthma and allergic reactions of the skin.

Glutaraldehyde does not normally occur in urine and is readily detectable. It will interfere with the immunochemical screening tests. It may also interfere with the recovery of the drug in GC/MS analysis or it may destroy the metabolite. It is interesting to note that, although this product is sold as a way to guarantee a negative in the urine of marijuana users, it affects the analysis of other drugs as well. It has a chemical aldehyde smell and it will denature proteins in the urine, so that over a 1- or 2-day period of time a brown precipitate will appear. No matter what the preliminary basis may be for suspecting adulteration of a specimen by glutaraldehyde, the presence of glutaraldehyde should be confirmed by reliable chemical analysis such as GC/MS. Glutaraldehyde at any detectable level in a urine specimen is evidence of adulteration.

Clear Choice is another adulterant containing glutaraldehyde and squalene.

10.7.7.7 Other Chemicals and Household Products

Surfactants, including ordinary detergents, have been used to adulterate urine specimens. Surfactants have a particular molecular structure made up of a hydrophilic and a hydrophobic component. They greatly reduce the surface tension of water when used in very low concentrations.

Foaming agents, emulsifiers, and dispersants are surfactants that suspend an immiscible liquid or a solid, respectively, in water or some other liquid.

Liquid Soap: Reported to cause false negatives in EIA procedures for THC and PCP. Its addition increases the pH of the specimen. A commercial adulterant called Mary Jane SuperClean 13 was reported to be primarily soap.

Sodium Chloride: Reported to cause false negative in EIA procedures. Its addition increases the specific gravity and chloride ion content of the specimen.

Bleach: Reported to cause a false negative in EIA procedures for all five drugs tested for by SAMHSA and in FPIA procedures for all but cocaine.

Drano: Reported to cause false negatives in EIA procedures. Its addition increases the pH of the specimen.

Sodium Bicarbonate: Reported to cause false negatives in EIA procedures for opiates and PCP. Its addition increases the pH of the specimen.

10.7.8 The Invalid Result

HHS describes an invalid result as follows:

When a laboratory is unable to obtain a valid drug test result or when drug or specimen validity tests indicate a possible unidentified adulterant, the laboratory reports the specimen to the MRO as “invalid result.”

This definition is not a comprehensive. Invalid results also include a category of specimens that can be described as having suspect or abnormal characteristics, such as pH out of the normal range, high nitrite levels, or unusual creatinine and specific gravity levels. It is true that “invalid” results can indicate a possible unidentified adulterant or substitution and that many invalid results could not be physiologically possible. But in many cases there is just an absence of conclusive scientific evidence that the specimen is not physiologically possible, and/or that the analytical method is not definitive, precise, or valid enough to withstand legal challenge.

When an MRO receives an “invalid” specimen report, it is incumbent upon him or her to discuss with the laboratory whether additional tests should be performed by the laboratory or by another certified laboratory. It may be possible to obtain definitive drug test results for the specimen using a different drug test method or to confirm adulteration using additional specimen validity tests. The choice of the second laboratory or additional tests will be dependent on the suspect adulterant and the validated characteristics of the different drug test. Laboratory staff should be knowledgeable of their tests’ validated characteristics including effects of known interfering substances, and be able to recommend whether additional testing is worthwhile.

The current HHS specimen validity rules require screening of specimens for oxidants, but do not require the laboratory to confirm the screening results. The rationale is that requiring specific confirmation methods for a broad class of defined and undefined adulterants would represent a significant cost increase in laboratory services. The majority of laboratories have decided not to bother with confirming oxidant results, and simply report the screening results as “invalid.” Somewhat unanticipated is that even laboratories that were confirming common oxidants such as nitrites have withdrawn from this practice. The specimen validity rule requires the laboratories to have more comprehensive and definitive confirmatory procedures for nitrites. This likely requires the acquisition of additional laboratory equipment. In addition, there is significant time involved in confirming results of any type. In the wake of increased litigation, there are lingering liability concerns at the laboratories. The end result is that only a small number of laboratories perform confirmatory procedures for nitrites and other oxidants as required by the current rules.

So today there have evolved three conceptual categories of laboratory results: the positive (drug, adulterated, and/or substituted), the invalid (everything in between), and the negative (dilute and non-dilute). Each requires the focus and attention of the laboratory and the MRO.

10.8 THE ROLE OF THE MEDICAL REVIEW OFFICER IN WORKPLACE DRUG TESTING

Joseph A. Thomasino, M.D., M.S., FACPM

JAT MRO, Inc., Jacksonville, Florida

10.8.1 The MRO as the “Gatekeeper” of the Workplace Drug Testing Program

A Medical Review Officer (MRO) has come to be defined in U.S. Department of Transportation (DOT) regulations (i.e., 49 CFR Part 40) as a licensed physician (Doctor of Medicine or Osteopathy) who is knowledgeable about and has clinical experience in controlled substance abuse disorders, including detailed knowledge of alternative medical explanations for laboratory confirmed drug test results. The MRO has become an integral part of the workplace drug testing process as federal regulations for workplace drug testing have been developed and implemented, at first for drug testing of federal employees, and then for millions of other workers in private industry for which drug testing was mandated by federal agencies such as the U.S. DOT, The U.S. Coast Guard, and the Nuclear Regulatory Commission. Beginning in the mid-1980s the MRO has been involved in an ever-growing number of drug tests. Federal regulatory requirements for workplace drug testing have expanded and these regulations have further defined and broadened the role of the MRO in the process. Programs for workplace drug testing requiring medical review have been implemented by various states (e.g., Florida, Georgia, others) in connection with worker compensation programs. Some states have required medical review of all workplace drug tests results collected in those states (e.g., Oklahoma and New York). Increasing numbers of private employers have been implementing drug testing programs that include medical review of results absent any regulatory requirement to do so. Although originally all workplace drug testing programs involved the collection of urine drug testing specimens, and most still do, other sampling media including hair, blood, saliva, sweat, and others are beginning to be accepted and used in workplace drug testing programs. All of these factors have led to the emergence of the MRO as the “gatekeeper” of the workplace drug testing process.

The identification of the MRO as the “gatekeeper” in the workplace drug testing process was first made in DOT regulations. It is an apt characterization of the overall role of the MRO in this process. One way to conceptualize this role is to consider that the MRO is an “equity agent.” In a sense the MRO oversees all the elements of the process. The MRO ensures that the donor (i.e., the individual providing the drug testing specimen) has had the specimen collected properly, that it has been analyzed correctly, that the result has been reported to the MRO promptly and clearly, that alternative medical explanations for any positive or other non-negative results where appropriate have been sought, that the donor’s technical questions have been answered and the donor’s response to an adverse determination (e.g., a reconfirmation test, substance abuse professional evaluation, etc.) has been facilitated, and that a prompt and clear report of the final determination/verification has been made to the employer or other organization commissioning the drug test. By performing the above functions in reviewing each drug test the MRO helps confer legitimacy and fairness to a process that can become contentious as serious sanctions are often applied to donors with verified non-negative results. A verified positive result, or a determination that the donor has refused to provide an adequate specimen for drug testing, may result in denial or termination of employment,

loss of other benefits, or other adverse outcomes for the donor. Thus the role of the MRO in allowing the donor due process to explain properly collected and technically valid drug testing results before an adverse determination is made has become vital in maintaining the integrity, value, and effectiveness of workplace drug testing programs.

10.8.2 The MRO and the Collection Process

Proper collection of drug testing specimens is the first and arguably the most critical step in the implementation of any workplace drug testing program. Important in this is that chain-of-custody procedures be established and followed in collecting drug testing specimens. Given the serious consequences for the donor that often follow adverse determinations, and the concomitant risk for the organization commissioning the test in applying those consequences inappropriately, it is clear that before becoming involved in the review of any drug test the MRO must be sure that appropriate chain of custody procedures were followed in the collection and further handling of the specimen as it is transported to and analyzed at the laboratory. Strict adherence to the appropriate collection protocol with close attention to properly establishing, maintaining, and documenting the chain of custody for each specimen is therefore vital to the overall success of any drug testing program.

The MRO is rarely, if ever, actually present at the time any specimen is collected. In most instances the MRO does not actually know, and has never met the collector for any given specimen. Therefore as the “gatekeeper” of the process the MRO must rely on review of the chain of custody and control form (CCF) that has been completed by the collector and the donor at the time the specimen is collected. Needless to say, prompt provision of a legible copy of the CCF to the MRO by the collector is absolutely vital for the proper management and promulgation of any drug testing program. Practically speaking, assuring that a legible copy of the CCF for each specimen is obtained as rapidly as possible after a specimen has been collected is a major activity for the MRO and staff. The success of most MRO practices, and the ability to gain and maintain clients by the MRO, is largely determined by how rapidly the MRO is able to provide reports of final determination/verification to the organization commissioning a test, once a test has been collected.

Once received, the CCF for each specimen is reviewed by the MRO or staff to ensure that it is legible and that it has been appropriately completed by the collector and the donor. The legible, properly completed CCF is then matched with the result received from the laboratory and the MRO and/or staff complete the review and make report to the organization commissioning the test. Any deficiencies in the CCF should be corrected, if possible, by the MRO before the final determination is made. Often deficiencies will have been detected and corrected by the laboratory before the result is reported to the MRO. However, if it becomes apparent that the laboratory has failed to detect or correct a deficiency it falls to the MRO to do so.

Certain flaws on the CCF are “fatal.” The most common of these are quantity of specimen insufficient for testing; no collector printed name or collector signature in the collector certification portion of the CCF; tamper-evident seal broken or missing on the specimen container upon arrival at the laboratory; and donor identification on the specimen container not matching the donor identification on the CCF submitted with the specimen. When these “fatal” deficiencies or flaws are detected the laboratory will not perform the analysis. When this condition is reported to the MRO the final determination/verification must be that the test was canceled due to the flaw. However, for other deficiencies, if the laboratory has not corrected them, the MRO must do so. These include, among others, a CCF on which the collector’s name is printed but the collector has failed to sign that section of CCF in which the collector certifies that the specimen was submitted by the donor in question and that the specimen was collected, labeled, and sealed in accordance with the appropriate protocol; the certifying scientist has failed to sign the laboratory copy of the CCF when reporting the result (this becomes apparent to the MRO only in the case of a non-negative result for which the laboratory copy of the CCF must be provided to and reviewed by the MRO prior to making a final determination/verification); and times and/or dates on the CCF missing

or contradictory. There is at least one flaw or deficiency that cannot ordinarily be corrected by the laboratory prior to analysis. This is failure of the donor to sign that section of the CCF in which the donor certifies that the specimen was actually submitted by the donor, that it has not been adulterated or tampered with, that the specimen container was sealed with a tamper-evident seal in the donor's presence, and that the information on the CCF and the label affixed to the specimen container is correct. As the laboratory ordinarily does not receive a copy of the CCF that bears the donor's signature, it is the MRO's responsibility to check for and correct this deficiency when it arises. Unless the collector has noted in the remarks section of the CCF that the donor has refused to sign, or that the collector forgot to have the donor sign before leaving the collection site, an attempt should be made to correct the flaw. This flaw, like other flaws that can be corrected, is corrected by having the collector sign an affidavit, certificate of correction, or memorandum for record (these are synonymous terms). This document should indicate that despite the flaw, the specimen was, in fact, submitted by the donor in question, the specimen was otherwise collected, handled, and transported to the laboratory properly, and that this is a true and accurate statement on the part of the collector. Once the properly executed document is received by the MRO it is maintained with the other documentation for the specimen, and review proceeds as for any other specimen. If the deficiency is not corrected in a reasonable time, usually considered to be no more than 1 to 2 weeks from when the flaw was detected and the certificate of correction was presented to the collector, the specimen is reported as canceled due to the uncorrected flaw.

When "fatal" or uncorrected flaws result in the cancellation of a specimen, it is the responsibility of the MRO to document and point this out to the collector in question, urge the collector to ensure that the situation is not repeated, and suggest that if additional training or education is needed to address the situation and prevent recurrences that it be promptly obtained by the collector. Even minor deficiencies or administrative mistakes that do not cause cancellation of the test, or require formal correction per se, in order to make a final determination/verification, should be documented and pointed out to the collector for corrective action. Errors of this sort that have no significant adverse effect on the donor's ability to have a fair and accurate drug test include among others: failure of the collector to indicate whether the specimen temperature was read within 4 min of collection and/or whether or not the temperature was within range; minor mistakes in recording the donor identification number on the CCF; reason for test inappropriate or unmarked on the CCF; failure to directly observe a specimen in instances where observation was called for; and delay in the collection process.

By careful review of the CCF for each specimen the MRO helps ensure the integrity of the collection process, and by extension the entire drug testing process, as proper collection is the foundation of any successful workplace drug testing program. By correcting deficiencies that are detected and making collectors aware of them, the MRO strengthens and fosters this most important element of workplace drug testing programs.

10.8.3 The MRO and the Analytical Laboratory

In a sense the MRO is one of the main "customers" of the analytical laboratory performing toxicological testing in the drug testing process. Although the organization commissioning the test may actually originally arrange for and pay for drug testing, in most instances the analytical laboratory reports results directly to the MRO who makes a final verification of the results before reporting them to the organization commissioning the test that has engaged the MRO for this purpose. In most instances where an organization has engaged an MRO the organization is not made aware of the laboratory confirmed result by the laboratory and the laboratory will not reveal the laboratory confirmed result to the organization, insisting that the MRO report all results to the organization. This arrangement is required for federally mandated testing and by some state-sponsored testing programs, e.g., in Florida. In other states either all results or only laboratory confirmed positive results (e.g., in Maryland), must be reviewed by the MRO before they are

reported to the organization commissioning the test. Therefore, in practice, the MRO and staff usually develop close working relationships with their counterparts at the analytical laboratories, i.e., the toxicologists, certifying scientists, and client service representatives. This is necessary to ensure prompt receipt of results by the MRO once analysis has been completed and for the MRO and staff to clarify and fully understand all aspects of the laboratory report.

As the “gatekeeper” in the drug testing process the MRO has a responsibility to correct any flaws in the testing process that may be discovered on the part of the analytical laboratory before making a final determination for any given test result. Failure of the certifying scientist to provide necessary documentation (e.g., the properly completed laboratory copy of the CCF for non-negative results on federal testing), failure of the certifying scientist to sign or otherwise fully and properly complete necessary documentation, and correction of flaws in the collection process not detected by the analytical laboratory prior to release of results to the MRO are examples of this.

The MRO has a responsibility to ensure that all aspects of the laboratory report are understood before making a final verification. This is particularly important when invalid drug test results are reported by the laboratory. In these instances, where for a variety of technical reasons the toxicologist does not feel that a reliable analysis can be made (e.g., presence of an interfering substance the exact nature of which is unknown, urine specimen colored blue or having some other unusual color or appearance, urine creatinine low with normal specific gravity, among others), the MRO must interview the donor to establish whether or not a legitimate medical explanation can be established to explain these circumstances. It is incumbent on the MRO to fully understand why the specimen was deemed unsuitable for analysis rendering the invalid result, and to consult with appropriate laboratory personnel in this regard, so as to properly direct the interview with the donor. Similarly, there are instances where it is not clear to the MRO whether a donor’s explanation for any non-negative result would in fact explain the result. The MRO can and should consult with appropriate laboratory personnel in these instances and make reliance on the information and guidance they provide in these matters.

Finally, the MRO often has a responsibility to offer the donor the option to have a drug testing specimen with a non-negative result sent to a different analytical laboratory for reconfirmation testing after an adverse determination has been made for that result by the MRO. This is required for federally mandated drug testing, by some state sponsored drug testing programs, by state law in some states, and as a matter of organizational policy for some organizations commissioning drug testing. As the “gatekeeper” of this process, if a specimen fails to reconfirm for the result in question, the MRO has a responsibility to then amend the final determination/verification for that specimen. The MRO must also notify the donor and the organization commissioning the test of this, and depending on the type of testing, e.g., federally mandated, state sponsored, etc., may also have to make a report to a governmental or other body overseeing the drug testing process. Such a report may have serious consequences for the analytical laboratory found to have reported a “false positive” or other erroneous result in terms of the laboratory’s ability to continue to provide drug testing services.

In practice the MRO and staff must develop and maintain good communications and close working relationships with their counterparts at the analytical laboratories. This is essential for the proper conduct of any drug testing program.

10.8.4 The MRO and the Verification of Drug Testing Results

The primary role of the MRO in workplace drug testing programs has always been to verify the results of the drug tests collected. When federally mandated drug testing programs were first implemented in the 1980s it was considered essential that donors with laboratory-confirmed positive drug testing results be afforded an opportunity to confidentially provide a legitimate alternative medical examination, if one existed, before the commissioning organization learned of the result. In the event that a legitimate alternative medical explanation could be established, the laboratory-confirmed positive result would be “downgraded,” i.e., reported as negative to the

commissioning organization by the MRO in such a way that it would appear to be no different from any other laboratory-confirmed negative result. As part of allowing “due process” before sanctions were applied to the donor as a result of a laboratory-confirmed positive result, the role of the MRO as the finder of fact, interpreter of information offered, and maker of the final determination was conceived.

A large portion of the time an MRO devotes to MRO practice is spent conducting and interpreting the results of interviews conducted with donors with laboratory-confirmed non-negative results. Originally, these were individuals with laboratory-confirmed positive results for the five drugs or classes of drugs tested for in federally mandated testing, i.e., amphetamine and methamphetamine, cocaine metabolites, marijuana metabolites, opiates (specifically codeine, morphine, and 6-acetylmorphine), and phencyclidine. As non-federally regulated drug testing programs were implemented, expanded, and in some cases tailored to the needs of individual organizations, other substances including alcohol, barbiturates, benzodiazepines, methadone, methaqualone, other opiates, propoxyphene, and others have been included in workplace drug testing programs, and naturally the MRO has had to deal with laboratory-confirmed positive results for these as well. In this process the MRO confidentially conducts and documents the interview; explains the result to the donor and the MRO’s role in the process; allows the donor the opportunity to present an explanation; gives the donor reasonable time to develop and provide any evidence supporting any explanation offered; and promptly reviews, interprets, confirms, and verifies any information received before making the final determination/verification.

Besides laboratory-confirmed positive results, other non-negative results have also come to require an interview of the donor and interpretation of information gathered prior to verification by the MRO. For federally mandated testing, urine specimens that have been adulterated with a foreign substance that can be specifically and reliably identified are reported as such to the MRO by the laboratory. The MRO conducts an interview to determine if a legitimate alternative medical explanation can be established for the presence of the adulterant in the specimen. If this cannot be established, the result is reported as a “refusal to test” to the organization commissioning the test with resultant sanctions applied to the donor as prescribed in federal regulations. For federally mandated testing, urine specimens with extremely low creatinine levels (i.e., 2 mg/dl or less) and specific gravity of 1.001 or less or 1.020 or greater are reported as substituted (i.e., not consistent with normal human urine) to the MRO. Similar to adulterated specimens, for substituted specimens the MRO must also conduct an interview to determine if a legitimate alternative medical explanation can be established to explain these abnormal creatinine and specific gravity values. If it appears to the MRO that such an explanation may exist, the donor is then required to demonstrate under observed and controlled conditions that urine with these abnormal characteristics can once again be produced. The MRO reviews the results of this procedure in making the final determination. Once again, failure to establish an acceptable explanation or to demonstrate the production of urine meeting these criteria under observed and controlled circumstances will result in a final verification of the result and report to the commissioning organization as a “refusal to test.” Invalid drug test results, as discussed above, also require an interview with the donor. In these if a legitimate alternative medical explanation can be established, the result is simply verified as canceled with no further action required unless a negative result is required (on federally mandated testing this is for pre-employment, return to duty, or follow-up testing). If a legitimate alternative medical explanation cannot be established, the test is verified as canceled but on federally mandated testing the organization commissioning the test is informed that an immediate re-collection directly observed by an individual of the same sexual gender as the donor must be conducted with minimal advance notice to the donor.

There are some additional circumstances that require review by the MRO of information not gathered directly from the donor or provided by the analytical laboratory. Results of evaluations conducted in response to substituted specimens were mentioned above. For opiate positive results (i.e., codeine or morphine) the MRO in some circumstances (6-acetylmorphine negative, and

codeine or morphine level less than 15,000 ng/ml on federally mandated urine drug testing) the MRO must have clinical evidence of opioid abuse before making a final determination/verification that the test is positive. This involves in some cases a “hands on” physical examination conducted by the MRO, or review by the MRO of an examination conducted by another physician acceptable to the MRO, to establish whether or not there is clinical evidence of opioid abuse (e.g., needle marks or tracks, disturbance of the sensorium, neurological abnormalities, etc.) before making the final determination/verification. Individuals who do not provide sufficient urine for testing even when provided extra time and fluids to do so are putatively demonstrating so-called “shy bladder.” In these cases, on federally mandated testing, the donor is required to undergo an examination by the MRO or other qualified physician acceptable to the MRO to establish whether or not an ascertainable physiologic condition (e.g., a urinary system dysfunction) or a documented preexisting psychological disorder had or with a high degree of probability could have prevented the donor from providing a sufficient quantity of urine for testing. The MRO must review the results of this evaluation, seriously consider the opinion of the examiner if the examination was conducted by another, and render a final determination. If there is an acceptable explanation established as a result of the examination the test is verified as canceled unless a negative result is required; if there is no acceptable explanation established it is reported as a “refusal to test.” On federally mandated testing where a negative result is required and the test is canceled due to an established legitimate explanation, an additional examination of the donor is required to establish whether not clinical evidence of illicit drug use also exists. The results of this examination, conducted once again either by the MRO or another physician acceptable to the MRO, are reviewed by the MRO and a final determination is rendered. This evaluation may also include drug testing using another medium such as blood, saliva, hair, etc. If there is no evidence of illicit drug use, the test is verified as negative and is so reported to the organization commissioning the test. If there is evidence of illicit drug use, the test is reported as canceled and the evidence of illicit drug use is also reported to the organization commissioning the test.

Although the personal focus of the MRO is naturally on non-negative results, the vast majority of results reviewed by the MRO and staff are negative. The MRO has a responsibility to ensure that negative results are also properly reviewed and promptly verified and reported as negative. The concerns expressed above concerning collection and laboratory issues apply to negative results as well. Regular, periodic review by the MRO of negative results verified by staff is required for federally mandated testing, and is an essential element of good MRO practice in general.

The heart of the MRO’s practice and professional responsibility is timely, accurate, and equitable review, verification, and reporting of drug testing results. The integrity, credibility, and success of this vital public safety and health program depend on the responsible and proper performance of this function by professionals dedicated to it.

10.8.5 The MRO and Safety Issues

Often, during the interviews conducted for non-negative results, the MRO will be informed by the donor, or will otherwise learn through other information provided as part of this process, of a condition the donor is suffering or a medication the donor is taking, that either renders the donor medically unqualified for safety-sensitive work in terms of the federal regulation in response to which drug testing is being conducted or which otherwise poses a potential safety hazard to the worker, co-workers, or the general public. Many of these federal regulations, e.g., those of the DOT, require the MRO to report these circumstances to the employer or other organization commissioning the drug test, without the consent of the donor. Some state-sponsored drug testing programs, e.g., the Florida Drug-Free Workplace Program, include similar provisions. In general, it is common for the MRO to feel obligated to report such circumstances to the organization commissioning drug testing even when not required or encouraged to do so by any extant federal or state law, regulation, or guideline.

Obviously, such a report will usually have serious consequences for the donor as it may result in the donor being prohibited from performing all or part of the donor's work duties until the situation is resolved. DOT regulations, for example, currently require the MRO to report the safety issue to the employer. However, these regulations also require the MRO to instruct the donor that if additional information is provided to the MRO in a timely fashion from the donor's treating health practitioner that modifies the situation the MRO must then share that with the employer for the employer's further consideration of the matter. A similar approach may be adopted by the MRO for non-federally mandated testing in an attempt to resolve these potentially serious and often contentious issues.

This issue has been complicated by the Health Insurance Portability and Accountability Act (HIPAA). Some information obtained during the MRO interview or other portions of the drug testing process may be considered "protected health information" and therefore under HIPAA would require specific consent or authorization from the donor before it was released by the MRO to the organization commissioning the test. The DOT has opined that such information gathered as part of the drug testing regulated by that agency is exempt from the provisions of HIPAA, and that the MRO, and other service providers, need no consent or authorization to release information gathered during this process in accordance with the federal regulation. However, for state-sponsored programs, or other non-federally mandated testing, it is not at all clear that "protected health information" gathered during the process of drug testing can be released by the MRO or other service providers to the organization commissioning the test in the absence of the consent or authorization of the donor without running afoul of HIPAA. In some states, for example, Maryland, certain information gathered as part of the drug testing process cannot be released to the organization commissioning the test without the donor's consent or authorization as a matter of state law, over and above any requirements imposed by HIPAA. Until this issue is clarified, and in some states regardless of any interpretations or modifications of HIPAA, it would appear most prudent for the MRO to obtain specific written consent from the donor before releasing "protected health information" to the organization commissioning the test, unless as is the case for DOT testing the issue has been specifically and definitively addressed. In practice, this may be accomplished *ad hoc* on a case-by-case basis as the need arises, or by advising the organization commissioning the test to require an appropriate written consent or authorization be executed by the donor before drug testing is performed.

10.8.6 The MRO and Other Administrative Functions in Workplace Drug Testing

The MRO may be called upon to perform a number of administrative functions beyond simply reviewing and reporting of results.

As discussed above, additional examinations of donors may be required before the MRO can make a final determination/verification in certain instances. For federally mandated testing donors with shy bladders (i.e., not able to produce a sufficient quantity of urine for testing), donors whose inability to produce a sufficient quantity of urine for testing is due to a permanent or long-term condition and for whom a negative result is required (i.e., on pre-employment, follow-up, or return to duty testing), those with adulterated or substituted specimens under certain circumstances, and donors for whom clinical evidence of opioid abuse must be obtained, will require the MRO to approve of the selection of the referral physician other than the MRO for these examinations, and in some instances help either the organization commissioning the test or the donor to locate a suitable examiner.

On federally mandated testing the MRO has a responsibility to cooperate with the Substance Abuse Professional (SAP) working with a donor for whom the MRO has verified a result as positive, or refusal to test. The MRO must also provide available information that the SAP requests, e.g., quantitative test results, information gathered during the MRO interview, etc.

The requirement on federally mandated testing for the MRO to report medical information to the organization commissioning the test that is likely to result in the donor being determined to be

medically unqualified for safety-sensitive duties, or otherwise indicates that continued performance of safety-sensitive duties by the donor is like to pose a significant safety risk, has also been mentioned above. Prompt sharing of additional information received from the donor's physician that might modify such a situation with the organization commissioning the test is an important administrative function the MRO is called upon to perform.

For all forms of testing the MRO has a responsibility to preserve the confidentiality of all information gathered and maintain records of MRO activities for varying periods of time depending upon regulatory requirements, state laws, contractual obligations, and professional guidelines. The MRO may also be called upon to provide these records to individual donors and produce them in various court or other legal or administrative proceedings.

Finally, in practice, the MRO is often called upon as a general consultant source for all matters dealing with drug and alcohol testing, not only by employers, but also by labor organizations and individual donors with concerns about drug testing. The MRO may be called upon by the organization commissioning the test to help arrange and review specialized toxicological testing tailored to some particular circumstance or situation in the workplace. Perhaps the most important administrative function for the MRO is to be knowledgeable and available to employers and donors to address their questions and concerns so as to support the integrity and credibility of the drug testing process.

10.8.7 Emerging Issues for the MRO

A number of issues are currently emerging that will affect MRO practice. These include specimen validity issues, alternative testing matrices, expanding the scope of toxicological testing on federally mandated and other testing, and on-site testing.

Concerns have been raised as to the level of creatinine in the urine that when present with a specific gravity of 1.001 or less or 1.020 or greater is to be considered evidence of a substituted specimen, not consistent with normal human urine, and thus exposing the donor to sanctions if such a specimen is verified as a refusal to test on this basis. Formerly this level was 5 mg/dl or less. However, quite recently, in response to scientific review of this issue and demonstrated ability on the part of donors to produce creatinine levels of 3 to 4 mg/dl simply by ingesting fluids, with no underlying physiologic disorder, DOT has lowered the level at which the specimen is to be considered substituted by the MRO to 2 mg/dl. Formerly, negative specimens were considered substituted with levels of creatinine between 2 and 5 mg/dl. These required the MRO to interview the donor, and in the absence of conditions that would lead the MRO to believe there was a reasonable probability that such levels of creatinine and specific gravity could be produced physiologically by the donor, verify the result as a refusal to test. These are now to be verified by the MRO as negative and dilute with the requirement that the specimen be re-collected immediately under direct observation by an observer of the same gender as the donor. This issue will continue to be controversial and additional changes to the approach to the problem of ultradilute specimens may very well be forthcoming as experience and research expand. Needless to say, any such changes are bound to affect MRO practice.

As noted above, urine has been the traditional medium or matrix for drug testing. Most workplace drug testing programs still collect urine. Currently, federally mandated alcohol testing utilizes breath or oral fluid (i.e., saliva) specimens. At present, for federally mandated drug testing only urine specimens may be collected, with the exception of instances where the donor is unable to produce sufficient urine for testing due to a permanent or long-term medical condition and a negative result is required. However, additional matrices are emerging that are gaining greater acceptance and wider use. Blood has always been available, but the invasive collection method and the greater expenses involved have relegated it to a very minor role in workplace drug testing programs. More recently, hair testing has been implemented in a number of state-sponsored (e.g., Florida) or other unregulated programs. Oral fluid testing is being offered by analytical laboratories

for unregulated testing and some companies are starting to adopt it. On the horizon are other matrices, including sweat, that may also emerge as practical media for drug testing. The MRO will have to become familiar with the pitfalls and nuances of interpretation of results obtained from these alternative matrices.

The scope of workplace drug testing has largely been confined to the ten drugs or classes of drugs mentioned above. However, changes in the drug of choice of some members of industrial populations over time are being noted and calls for an expansion of the drugs tested for on regulated and unregulated testing are being increasingly made by employers and other organizations commissioning testing. At present there is pressure to include methylenedioxymethamphetamine (MDMA or “ecstasy”), gamma-hydroxybutyric acid (GHB or “Georgia home boy”), Rohypnol (flunitrazepam or “the date rape drug”), OxyContin (oxycodone), and others in standard drug testing panels. Obviously as the scope of drug testing expands this will increase the challenges faced by the MRO.

Workplace drug testing has traditionally been based on collecting a specimen at or near the workplace. The specimen is then sent to an analytical laboratory distant from the workplace. The results of the analysis have then been reported to the MRO who has reviewed them before they are released to the employer or other organization commissioning the test. Currently, federally mandated drug testing must be done in this way. However, new systems of testing have been developed that permit reading of the result immediately after collection at the workplace. In practice, most organizations performing this on-site drug testing will immediately act on negative results without any further testing, e.g., permitting a pre-placement applicant to begin work immediately, etc. Specimens demonstrating non-negative results upon on-site testing are usually sent to an analytical laboratory for confirmatory testing. If results are confirmed as non-negative, definitive action is then taken in response to the confirmatory testing done off-site. The accuracy, sensitivity, and specificity of the various on-site testing systems currently available vary, and approach the accuracy, sensitivity, and specificity of traditional analytical laboratory testing to varying degrees depending on the system used. Depending on the design of the system there may be no role at all for the MRO in the review of negative results of on-site testing, with MRO review being reserved for non-negative results that are confirmed as non-negative as described above. To what degree and in what fashion the MRO is to be integrated in on-site testing will obviously be of great interest as use of on-site testing grows.

10.9 QUALITY PRACTICES IN WORKPLACE TESTING

John M. Mitchell, Ph.D. and Francis M. Esposito, Ph.D.

Health Science Unit, Science and Engineering Group, RTI International, Research Triangle Park, North Carolina

10.9.1 History

The roots of workplace drug testing lie in the U.S. military’s drug testing program. The military began drug testing military personnel in response to the rise in drug abuse that accompanied the Vietnam War. Initially, it was designed to identify “at risk” individuals and to present an opportunity for treatment. By 1980, drug abuse in the U.S. military was rampant. A survey found that approximately 50% of enlisted personnel had used illicit drugs within the past 10 days.¹ It was obvious that more stringent measures were necessary. At first, the military turned to the resources available in the civilian laboratory community, but it soon recognized that the methodologies available for the testing of the large number of specimens needed to support military goals were woefully

inadequate. A taskforce consisting of civilian advisors, testing industry representatives, and military personnel was organized to develop a system that would allow testing of large numbers of urine specimens in a forensically defensible manner. It was through these measures that modern-day forensic urine drug testing laboratories were created. These efforts are notable, because the military system established the basis for legal and scientific acceptance of the methods and procedures utilized in today's workplace drug testing. Important innovations in the military's program include random testing of personnel and instrumented on-site testing. This integrated program resulted in a reduction in drug use by enlisted personnel such that by 1982 a survey found that the number of personnel who used drugs in the past 30 days had dropped to less than 30%. By 1988, the number dropped to less than 10%.²

The military drug testing program was built upon the experience obtained from mass testing of biological samples in the clinical laboratory and forensic principles. While the primary purpose of the military's program was to maintain national security by removing personnel who were abusing drugs, it incorporated a quality system to protect service members from inaccurate results. The quality system that provided reliable testing included: observed collection of urine specimens, written standard operating procedures (SOPs), separate testing methods for initial and confirmatory tests, mass screening with immunoassay tests, confirmation of immunoassay positives by gas chromatography/mass spectrometry detector (GC/MS), utilization of deuterated analytes as internal standards for GC/MS procedures, internal and external quality control systems, independent assessment of laboratory performance by a team of experienced scientists, and the right of an accused to have a portion of the specimen retested.

Workplace programs mandated by the federal government and many state governments have incorporated most of the quality assurance components from the military's system. One component, routine observed collections, has not been incorporated into these systems, and this omission has proved to be a problem for "urine only" based workplace programs. Unobserved collections have fostered an industry dedicated to the subversion of these programs by the provision of synthetic urine, negative human urine, prosthetic devices for the delivery of substitution products, oxidants, fixatives, peroxidases, acids, bases, and other substances that are intended to interfere with the testing methods.

10.9.2 The Need for Quality Assurance

The necessity for maintaining quality in current workplace drug testing programs becomes apparent when the potential impact of this testing is considered. In 2002, laboratories certified by the Department of Health and Human Services (HHS) tested an estimated 6 million urine specimens collected from donors under federal mandate and an additional estimated 23 million specimens collected under other workplace programs (source: data supplied by federally regulated laboratories that participate in the National Laboratory Certification Program, NLCP). With estimated positive rates of 2.5% in regulated programs and 4.8% in nonregulated programs,³ this would mean that in 2002, these laboratories reported an estimated 1 million results consistent with drug use. In order that innocent individuals do not lose their jobs, and are not denied gainful employment or placed under suspicion of drug use, the goal for quality assurance (QA) in workplace testing programs must be zero tolerance for errors. In the following sections, we review the parts of workplace drug testing programs that are critical to success, examine the programs and methods currently in place to measure the quality of the system, and provide some suggestions for future measurements.

10.9.3 Parts of the Workplace Drug Testing Quality System

To obtain a goal of zero errors, the quality system must encompass all parts of the workplace drug testing program. The people, the equipment and instruments, the materials, the methods, and the facilities utilized in all phases of the program must be considered.

10.9.3.1 The Employer

In workplace drug testing, the quality system begins and ends with the employer. Without proper planning, training, and guidance, the program developed by an employer may not meet the requirements mandated by law and other guidelines. The choices an employer makes in selecting collection sites, testing facilities, and Medical Review Officers (MROs) will undoubtedly influence program effectiveness. While cost is a consideration in making these selections, it should not be the only factor considered. It is important that each test result be supported by proper collection, accurate and legally supportable testing, and appropriate determination of drug abuse. Without these elements, the actions taken by the employer as a result of a drug test may not be in accordance with the law or other guidance, may place the employer in jeopardy, and may wrongly accuse a valued employee or a qualified candidate for employment.

10.9.3.2 The Donor

The donor is an important part of the quality process, but the controls that can be placed on the donor are limited in most programs by considerations of privacy and personal rights. While most donors are conscientious and trustworthy, the quality system must limit the opportunity for a small drug-using minority to subvert the test by substituting their specimen with another urine or other aqueous solution, diluting their specimen by adding water or drinking large amounts of water before collection, or adulterating the specimen with substances that are meant to interfere with testing.

10.9.3.3 The Collection

A specimen must be properly collected to ensure an accurate test. Quality practices need to be followed to ensure the identity and integrity of the specimen. The identity of the donor must be determined, and the link between the specimen and the donor must be maintained throughout the process. Once obtained, the specimen must be secure from tampering and handled under forensic guidelines. There should be no opportunity for subversion of the drug test by the donor, the collector, or the two in collusion. These practices apply to specimens collected for on-site testing or shipped to a testing facility.

Specimens collected for workplace drug testing must be closely scrutinized for the quality of the collection. A positive drug test or an abnormal specimen validity test must be able to withstand the challenges of an MRO, a donor, or a legal review. Components of a quality collection include the collector, collection site, collection materials, and collection protocol. One source of guidance for urine specimen collection may be found in the handbook published by the Substance Abuse and Mental Health Services Administration (SAMHSA).⁴ Some of the information in this section was obtained from this handbook, with a focus on the items critical to the quality of the collection process.

The Collector

A key element in a quality performance by a collector is training. A collector may be responsible for collecting one or more specimen matrices (i.e., hair, urine, sweat, and oral fluid) and may conduct on-site tests on some of these matrices. Collectors must be thoroughly trained in the collection process for each matrix. They must be trained not only for the routine collection, but also for problems that might arise during the collection (e.g., unacceptable specimen temperature, apparent adulterated specimen, insufficient amount of specimen). For collectors also conducting on-site testing, training must be specific for each on-site testing device. The training should include when and how to conduct the test, demonstration of testing proficiency, actions to take for borderline results, how to package specimens for shipment to a testing facility for additional testing, completion of documentation, and reporting of negative results.

Proper collector training begins with a qualified trainer. For urine collection, which is the most common matrix in workplace testing, a supervisor of the collection facility with previous experience typically assumes this responsibility; however, there are organizations such as the Drug and Alcohol Testing Industry Association (DATIA) that will also provide a standard course on specimen collection. With the introduction of other matrices and on-site testing into federal and state programs, all training programs may require changes. New initiatives between the testing and collection industries and controlling agencies will become necessary to ensure the validity of the specimens and the results of on-site tests. Training will need to be provided for each specimen type and each on-site test device. Training should go beyond the standard classroom lecture format. Error-free mock collections should be demonstrated for each specimen type, and testing proficiency using blind controls should be demonstrated with each type of on-site testing device. Written exams may also be part of the training program.

All training must be documented in a manner that can be easily reviewed and understood by an outside auditor. Minimally, documentation would include a description of the training, time of conduction, identification of the trainer, results of all examinations, and criteria for acceptable performance.

Beyond the initial training, a collector should be monitored for performance. Errors that occur during specimen collection or with the use of on-site testing devices require error correction training. For example, the Department of Transportation (DOT) requires collector correction training when errors in the collection process of urine specimens cause a test to be canceled.⁵ The DOT requires the collector to demonstrate proficiency in the collection procedure by completing one uneventful mock collection and two mock collections related to the error. The person providing the retraining attests in writing that the mock collections were performed correctly with no errors. However, this process fails to address frequency of errors, which is an indicator of the collector's overall performance and the potential for test-canceling errors.

Within the urine drug testing industry, the collection site is perceived to be the weak link in the quality system. To correct this perception, it is recommended that the performance of all collectors be monitored and training requirements be standardized. Within federal programs, one approach to monitoring collector performance would be to examine the chain-of-custody documents, commonly referred to as custody and control forms (CCF), completed by a collector. CCFs failing to conform to federal guidelines would initiate further assessment of the collector's performance and appropriate corrective actions. Examples of collector noncompliance would be submission of a single specimen when a split specimen is required, submission of two specimens with differing physical appearance as a split specimen collection, or submission of CCFs containing multiple administrative errors. Collectors for non-federal programs might be monitored by professional groups such as DATIA.

A collector's proficiency with on-site testing devices should be measured with periodic performance testing (PT) samples for each on-site device utilized, as well as routine submission of a percentage of the on-site negatives to a laboratory conducting instrumented immunoassay testing and confirmatory testing of immunoassay positives. Abnormal numbers of false negatives should then be investigated to determine if the cause is the on-site device or the performance of the tester. Federal programs should be able to monitor on-site devices and tester performance; however, other programs may have to rely on professional groups for this function.

Collection Site

A collection site must meet certain requirements to ensure a quality collection. The site must have restricted access. Collection materials, records, and specimens must be properly stored and secured from unauthorized individuals. Materials (e.g., controls, reagents, testing devices) must be kept in acceptable temperature and humidity conditions for proper performance. Secure storage must be provided for specimens until they are tested or shipped to a testing facility, and records

must be retained as required by applicable regulations. As part of its records, a collection site must maintain copies of current and past SOPs, a copy of each CCF, log books or log sheets, temperature logs from storage areas for specimens and perishable supplies, inventory of supplies/materials, donor information, and chain-of-custody handling. These records should be retained for the length of time required by governing regulations, usually 2 years or more. Urine collection sites should place bluing agent in the toilet bowl and tank and restrict access to soap, water, cleaning agents, and other materials that could be used to adulterate a specimen.

Collection Materials

A quality collection requires a collection kit designed for the matrix to be collected. The kit should contain a single-use collection device, container(s) for shipment of the specimen to a testing facility, CCFs, and tamper-evident seal(s). Kits for some matrices may require additional materials (e.g., scissors for a hair collection, wipes for a sweat collection). If on-site testing is to be conducted, the kit may also contain an on-site device. All materials must be proved not to affect the testing of the specimen. Containers used for storage/shipment must be capable of holding a tamper-evident security seal at room and frozen temperatures. Additional security can be provided to transported specimens with the use of individual sealable bags or boxes. Shipping containers can be used to protect the specimen from physical damage during transport.

Collection Protocol

A detailed written protocol (SOP) must be followed for every type of specimen collection. The basic requirements of a collection are the following:

- Preparation of the collection site (discussed above)
- Verification of donor identity
- Preparation of donor for specimen collection (e.g., removal of coats and hats for unobserved collections)
- Inspection of the specimen to ensure proper amount (and correct temperature of urine) and inspect for evidence of adulteration or substitution
- Preparation of the specimen for testing, storage, or shipment (e.g., sealing the specimen with tamper-evident labels)
- Completion of the CCF

The CCF is used to identify the donor, collector, employer, and MRO; to provide a unique specimen identification number; to account for handling of the specimen; and to report results and remarks in a uniform manner.

10.9.3.4 The Testing Facility

Testing facilities should establish QA programs to ensure the quality of their processes. Central to the quality assurance program is an SOP manual that details all procedures and processes. This manual and the documentation generated from a QA program in a workplace drug testing facility must be available for review by client auditors, certification agencies, lawyers, judges, etc. Users of the testing services in these facilities need to be assured that the results are high quality and legally defensible. A comprehensive QA program must include the handling, testing, and reporting processes. Components of QA practices include training personnel; validating and maintaining analytical instruments, analytical equipment, and computer systems; validating analytical methods; monitoring chain-of-custody procedures; using quality control samples; and participating in PT programs.

Personnel

Testing facility personnel must be well trained and motivated. They must not be allowed to succumb to the routine nature of the procedures utilized in today's high-throughput facilities. They must be knowledgeable of the scientific principles underlying the analytical procedures, the capabilities and limitations of the equipment they utilize to perform their work, and the regulatory requirements related to their work. They must be well versed in forensic principles and procedures, and their qualifications, training, and proficiency must be well documented.

Equipment and Instrumentation

The equipment and instruments utilized to test specimens are an intrinsic part of the quality system. They must be appropriate for the task and proven to perform the tasks through validation processes. This also includes the facility's management information system (MIS) and other computer-controlled equipment.

Materials

The importance of quality materials is often overlooked until a problem develops. As with equipment, the quality of the materials must be proven, not assumed. Quality facilities should perform acceptance tests on materials prior to their use and monitor their performance as a part of routine operations.

Methods

The methods utilized by a facility for all aspects of specimen handling and testing are a critical part of the quality system. A facility may have the best equipment available, highly motivated and trained personnel, and proven materials, but if the method is poorly designed, it will fail more often than a scientifically sound, operationally rugged method. Analytical methods and procedures utilized in workplace drug testing must be validated and characterized to provide timely results that will withstand the scrutiny of legal and administrative proceedings. Their continued performance at the desired level must be monitored by internal and external quality systems.

Basic Quality Assurance Practices

Method Validation — The quality of an analytical procedure is documented during its validation. Performance parameters commonly determined during validation of initial test procedures are linearity, specificity, precision, accuracy, and carryover studies. Validation of quantitative confirmatory procedures also includes sensitivity, limits of detection, and quantitation and ruggedness. Validation samples are prepared in the matrix to be tested and within the concentration range of interest. At a minimum, these tests are performed annually and when major changes (e.g., change in extraction procedure, new instrumentation) are made to an existing method. Validation records must be organized for an auditor's review and should include the purpose, scientific principle, method, results, discussion, summary, and review with approval by the facility director.

Quality Control — Quality control (QC) is a subsection of QA. QC is used to determine if all components of an analytical process are performing correctly. QC samples of known content are analyzed with the test specimens. Their purpose is to monitor the performance of an analytical procedure within defined limits of variation.

Calibrators are samples of known content by which the identification and concentration of an analyte in a specimen is determined. Calibration of a device or instrument can be established with a single calibrator or a series of calibrators at varying concentrations. It is common to find initial and confirmatory workplace drug tests evaluated with a single calibrator, but this approach requires the concentration to be determined at the administrative cutoff concentration or decision point. Multiple calibrators can be used to extend the limits of accurate quantitation on an instrument.

Calibrators and controls (often referred to as QC samples) are routinely prepared in the matrix of interest to minimize matrix effects. A quality practice is to prepare QC samples from a reference material of documented purity and content. Additionally, calibrators and controls should be prepared with reference materials from different suppliers; otherwise, a bias may occur. If both types of QC samples must be prepared from a single reference material, then they must be prepared independently.

QC samples must be validated before they are placed into use. The quantitative criteria for acceptance of calibrators should be more stringent than the criteria applied to other QC samples. Typically, calibrators should not differ by more than 10% from the target value, whereas controls may differ up to 20%. The primary method of validating new QC samples is by parallel testing with QC samples in use. If available, externally certified reference samples should be included in the validation process. The history and use of QC samples should be documented with information that includes the lot number, date of preparation and first use, expiration date, individual preparing the sample, preparation procedure, and validation data.

Workplace drug testing utilizes administrative cutoffs. QC samples at concentrations above and below the cutoff are used to demonstrate linearity around the cutoff, allowing clear differentiation of positive and negative specimens. These controls should be within the linear range of the assay and near the cutoff ($\pm 25\%$). Analytical batches should also contain a negative control to demonstrate the response of the assay in the absence of an analyte and a blind sample to demonstrate that the analytical batch has been properly prepared and analyzed. Other controls may be included to demonstrate extended linearity, lack of carryover, completeness of hydrolysis steps, lack of interference from structurally related analytes, and adherence to dilution protocols. Typically, a minimum of 5 to 10% of QC samples are required in each batch of specimens, some of which should be distributed throughout the batch.

Internal standards are essential to accurate quantitative analysis of QC samples and donor specimens. Ideally, the concentration of the internal standard should be close to the cutoff. Deuterated analogues of the analyte of interest are best for GC/MS selected ion monitoring as they have similar fragmentation patterns. However, structurally similar analytes can serve as the internal standard if the available deuterated internal standards are unsuitable (e.g., coelute with the analyte of interest and have the same major ion fragments).

Quantitative and qualitative acceptance criteria for initial and confirmatory tests must be established and adhered to during analysis. QC results, acceptable and unacceptable, must be documented as a complete record of QC performance. Systems for monitoring QC results should be established to detect shifts, trends, and biases. Actions to be taken to correct these anomalies should be contained in the facility's SOP.

Physical Plant

The physical plant in which testing occurs must be sufficient to meet requirements for security, habitability, safety, and performance of the work required. It must provide security for the specimen, the testing, and the results such that the linkage of the result with a donor is never in doubt. It must provide adequate space, ventilation, and other features to ensure a safe environment for employees and an optimum environment to conduct testing. Errors can be introduced in the testing process when the physical plant is inadequate.

It is important that an alternative source of power be available during prolonged power outages. At a minimum, there must be a plan to ensure proper temperature conditions for stored specimens.

Management Information Systems

An MIS is designed to improve the reliability, efficiency, and productivity of the testing facility. It may exist as a centralized data system with workstations tied into analytical equipment or stand-alone personal computers. It is used to log in and track samples, order tests, receive and manage data, report results, and handle routine administrative tasks. The MIS must be independently validated before being utilized for any task associated with the receipt, handling, testing, data review, or result reporting. All software and hardware added after the initial validation should be validated prior to use. Security must be in place to prevent unauthorized access, inappropriate release of information, and introduction of unauthorized, unvalidated software. The MIS must be monitored for problems, and audit trails must be established for all functions. Backup and disaster recovery procedures should be in place to prevent loss of information entered into the system.

MIS procedures should be subjected to routine audits as part of an inspection process. An MIS SOP manual describing the items above must be established and available during inspections. The person responsible for management of the MIS may not be the testing facility director; however, the director must be knowledgeable of the functions performed by the MIS, have input into its functions, and ensure that the forensic testing is supported. The testing facility director and MIS manager must work together to establish procedures for requesting changes to the MIS, validate changes, and determine end-user acceptance.

10.9.3.5 The Medical Review Officer

Testing facilities in all federal and many nonregulated workplace programs report test results directly to an MRO. Both DOT regulations⁵ and HHS Mandatory Guidelines⁶ contain requirements for MROs. To meet these requirements, physicians may obtain training and certification from any one of three organizations: American Association of Medical Review Officers, American College of Occupational and Environmental Medicine, and American Society of Addiction Medicine. To correctly interpret test results, MROs use their medical knowledge and their understanding of the applicable laws and regulations, the testing process, the collection process, and information provided by the donor. The properly trained and motivated MRO must be willing to question not only the donor, but also the collection site and the testing facility to ensure that the employer is provided a determination that considers the applicable science and regulations. MROs are often called gatekeepers because they are able to query the entire process to ensure that the quality system was intact.

The MRO practice should have a detailed SOP to ensure the quality of the MRO process, consistency of procedures, and adherence to governing guidelines and regulations. A more complete description of the MRO practice is described elsewhere in this volume.

Currently, MROs are not routinely monitored for the quality of their review. One approach to an MRO review program could be based on the documentation received by testing facilities. CCFs containing results for specimens reported as adulterated, substituted, invalid, and drug positive could be audited to determine the final disposition of the test. Reviews that revealed noncompliance with regulations would require an in-depth audit of other non-negative results reported by that MRO. Reports of these reviews could then be provided to the employer and other agencies, as appropriate.

10.9.4 Measuring Quality in the Workplace System

Measuring the quality of workplace testing requires the establishment of standards against which the measurement may be performed. Currently, there are four programs that establish

standards for testing facilities and conduct measurements against those standards. While there are programs that accredit or certify MROs and collectors, none conduct measurements beyond the initial certification or accreditation. Subsequent sections will describe some of the tools utilized by organizations to measure the quality of testing facilities.

10.9.4.1 Testing Facility Certifying and Accrediting Organizations

NLCP

The reliability of facilities that test specimens for drugs in the workplace will always be of concern. A high degree of certainty of results is required of drug testing facilities to prevent false accusations against those undergoing testing. For this reason, the “Mandatory Guidelines for Federal Workplace Drug Testing Programs”⁶ were developed to provide guidance to federal agencies for the collection and analysis of urine specimens collected from federal employees. With these Guidelines, HHS established standards for certification that have made HHS-certified urine drug testing laboratories the “gold standard” in the drug testing industry. Regulations issued by the DOT for the drug testing of safety-sensitive private sector employees in its operating modes, as well as the Nuclear Regulatory Commission for fitness for duty employees require the use of HHS-certified laboratories to perform their mandated drug testing.

The NLCP was developed for the establishment of initial and ongoing certification of forensic urine drug testing laboratories. The NLCP is designed to examine laboratories for compliance to the Mandatory Guidelines. In doing so, it examines the laboratory quality practices discussed above. Two of the major components of the NLCP are the PT program and the inspection program. Other components of the NLCP are described elsewhere in this volume.

The NLCP PT program emphasizes the laboratory’s ability to accurately quantify drug concentrations in urine and report the results following Federal requirements. Strict scoring policies mean that a certified laboratory’s failure to successfully test the PT samples may result in suspension or revocation of its certification. The NLCP challenges laboratories with PT samples formulated to mimic real specimens from donors in order to identify problems and to ensure appropriate actions are taken to correct those problems. Laboratories are expected to investigate all PT errors and must submit documentation of investigation and completed corrective action, as directed.

The NLCP categorizes laboratories (Category 1—smallest to Category 5—largest), using an objective system based in part on laboratory size, regulated specimen workload, and number of non-negative specimens reported in a 6-month period. Depending on category, semiannual maintenance inspections last 2 or 3 days and consist of one or two inspectors performing a general inspection (i.e., reviewing procedures and observing practice) and one to six inspectors performing a records audit. The NLCP focuses inspections on the procedures of the laboratory and on examination of the laboratory’s forensic product through the audit component. The teams use two checklists: the General Laboratory Procedures Checklist and the Records Audit Checklist. The inspection team submits two summary reports, one from the general inspectors and one from the auditors. The inspection reports are reviewed by the NLCP technical staff. An Inspection Final Report is returned to the laboratory listing the deficiencies. Major deficiencies require a remedial action plan within 5 business days. All others must complete the remedial process within 30 days. Remedial actions are reviewed at the next inspection.

College of American Pathologists

The College of American Pathologists (CAP) has developed a Forensic Urine Drug Testing (FUDT) Accreditation Program that parallels the NLCP but is directed at non-federal workplace drug testing. Although this is a voluntary program, many clients require this accreditation for their non-federal employee drug testing.

The CAP program requires completion of a self-inspection checklist between on-site inspections that are conducted by a group of volunteers in the forensic toxicology field. Inspectors, guided by a checklist, focus on laboratory procedures and processes that include specimen handling, analytical instruments and procedures, quality control, personnel, computer operations, safety, facilities, records, and reporting.

Laboratories are also required to participate in at least the Urine Drug Testing Confirmation PT program. Acceptable performance is based on correctly identifying and quantifying drugs and obtaining a minimum score of 80%. A false-positive drug report is a survey failure with accreditation probation. Continued failures result in loss of accreditation.

The FUDT program differs from the NLCP in that the laboratory is evaluated for drugs other than the illicit drugs used in the federal program. In addition, the laboratory may use initial and confirmatory cutoffs unlike those stated in the Mandatory Guidelines. A more detailed description of the FUDT program can be found in a previous edition of this textbook.⁷

State of Florida

The State of Florida has established a Drug-Free Workplace program similar to the HHS Program for Federal Employees.⁸ It regulates workplace testing for state employees and private workplace drug testing programs seeking discounts on Florida workers' compensation insurance premiums. Oversight of the program is maintained by the State Agency for Health Care Administration.⁹ It allows the testing of biological samples (primarily urine and hair) for ten drugs/drug classes and their metabolites and alcohol (blood). It requires laboratories to conduct initial and confirmatory testing of positive specimens using two different scientific methods, to participate in proficiency testing programs, and to report test results to an MRO. Laboratories must participate in a proficiency testing program that tests for all of the required drugs. Inspections of licensed laboratories are semiannual and are conducted by the state. An HHS-certified laboratory may request to substitute one of the state inspections with an NLCP inspection and is required to submit the results of all NLCP inspections. Blind PT specimens are not required as part of the QA program.

State of New York

The State of New York amended its public health laws in 1966 to require the licensure of clinical laboratories by establishing minimum qualifications for directors and by requiring that the performance of all procedures employed by clinical laboratories meet minimum standards accepted and approved by the state department of health.¹⁰ The laboratory licensure program is managed by the state's public health laboratory for 27 specialties of laboratory science, including forensic toxicology. The laboratory director must hold a certificate of qualification from the state department of health; minimum qualifications include a doctoral degree and 4 years of postdoctoral laboratory experience, 2 of which must be in the toxicology specialty. Laboratories engaged in the toxicological analysis of biological specimens are required to participate successfully in the state's proficiency testing program and must be in substantial compliance with standards of practice as assessed through biennial inspections. Laboratory standards and proficiency testing performance requirements in the forensic toxicology specialty are comparable to those of the NLCP. However, the State of New York has not imposed limitations on the specimen matrix, the drugs to be tested for in workplace programs, or the assay cutoff concentrations. These service characteristics are established through laboratory-client contracts. Performance in proficiency testing is evaluated in the context of the assay cutoff concentrations that are reported to the program. The proficiency testing specimen matrix is urine. Blind PT specimens are not required as part of the laboratory licensure program.

10.9.4.2 Methods of Measuring Quality

There are four primary systems for measuring the quality of a drug testing program: inspections, PT, blind specimens, and retests of non-negative specimens (conducted under most programs at the request of the donor).

Inspections

The inspection process is essential for improving and maintaining the quality of a testing facility, collection site, collector, and MRO. An inspection should represent an independent review of operations and be conducted by trained and knowledgeable professionals. It provides a means of peer review and feedback. Inspections provide a snapshot of the operations at the time they are conducted and are not a substitute for other quality systems. Since each part of the workplace drug testing system is dynamic, constantly changing to improve quality, increase efficiency, and reduce expenses, it is important that inspections occur on a regular basis. Although accreditation/certification may not be mandatory or available for each part of the system, it would provide additional assurance to clients that quality services and results are being provided. Currently there are no provisions for routine inspections of collection sites, collectors, and MROs.

Typically, inspections of a testing facility are a requirement for initial accreditation or certification, as are periodic maintenance inspections by certifying or accreditation organizations such as those previously described. Technically and professionally qualified inspectors receive training and continuing education sponsored by those organizations. The inspectors review all of the relevant administrative and technical functions of the site to ensure they are in accordance with prescribed regulations and industry practices. Inspectors, guided by an inspection checklist, review and evaluate testing processes to include: SOP manual, specimen handling, analytical equipment and maintenance, computer operations, analytical procedures, review and reporting of results, QCs, and personnel qualifications and training. Inspectors also review records that include specimen data, method validation data, PT data, chain-of-custody documentation, and reports transmitting results to the client or MRO. Deficiencies noted during the inspection must be corrected and reviewed at the next inspection.

A critical issue in any testing facility inspection is the amount of data that should be reviewed. The data should be carefully selected to optimize the detection of possible administrative, technical, and forensic issues. This is best accomplished by reviewing documentation and results for specimens that were reported as non-negatives. Non-negative specimens include drug positives, abnormal specimens (i.e., adulterated, diluted, and substituted), and specimens received but not tested. The resources required for an inspection should be determined by the testing facility's workload, the number of non-negative results reported, and the amount of review necessary to determine that all procedures have been adequately evaluated. Inspections meeting these criteria consume large amounts of time and resources, but are essential to maintaining quality.

Proficiency/Performance Testing (PT)

Participation in PT programs is an important quality practice for all testing entities, including testing facilities and personnel conducting on-site tests. They provide a mechanism for assessing the accuracy of the handling, testing, and reporting processes. They can be used to identify and test modifications to operating procedures, methods, and equipment. Regulatory agencies now require testing facilities to maintain acceptable performance in designated PT programs as a condition for initial and continued accreditation/certification. Although there are no regulatory requirements for routine PTs for on-site tests in workplace drug testing, some on-site testing facilities are using available PT programs to monitor performance.

PT samples are prepared by fortifying the matrix of interest (e.g., urine, oral fluids, hair) to the desired drug analyte concentration. Within workplace drug testing, PT samples are normally

formulated to determine the ability of the testing facility to accurately identify and quantify drug analytes alone or in the presence of possible interfering substances, to identify abnormal or adulterated specimens, and to determine the dynamic range of the testing methods.

PT samples should be handled in the same manner as donor specimens. This includes not using replicate analysis if routine samples are not run in replicate. Criteria used to identify and quantify specimens should be the same for donor and PT specimens. It is ideal for a testing facility to include PT samples among donor specimens when testing the samples.

Reported PT results from participating facilities are compared to a reference value (normally the average of all results excluding outliers) to determine acceptable quantitative performance. If different analytical methods are used, means for each method are sometimes determined for comparison. Appropriate ranges for each method's mean can be standard deviations, percentage from the mean, or both. Method means can be further used to determine acceptable methods and/or instrumentation when compared to established reference methods.

The number of specimens in a PT cycle is small in comparison to the total specimens analyzed in a facility. For this reason, a quality practice is to participate in as many PT programs as possible. It is desirable to spread these PT sets over the entire year.

Testing facilities should review the information returned by the PT program. Any trends that are developing should be examined. Unacceptable results are to be investigated and corrective action taken to prevent reoccurrence. For major errors (e.g., false positives, large variations from the reference value), immediate resolution of the error through remedial action should be required by the certifying/accreditation agency.

Do PT programs make a difference in performance? Analysis of data from the NLCP PT program indicates that a PT program can enforce an initial level of performance and over time improve the performance of conforming facilities. In Figure 10.9.1A, bar graphs depict, through average coefficients of variation (CV), the performance of laboratories that applied for certification and certified laboratories in 1990. The variation within the population of certified laboratories was less than that of the candidate population for all drug analytes. In Figure 10.9.1B, it can be seen that since 1990, the average CV for most drug analytes has decreased. Not shown are the average CVs for codeine and phencyclidine, which have remained at 9 to 12% since 1990.

Blind Specimens

QA specimens presented to a testing facility in the same manner as donor specimens are referred to as blind specimens. They are submitted with fictitious information on the required custody documents and specimen bottles. These specimens should not be readily identifiable as blind specimens. The drug content of a blind specimen should be validated before use.

The HHS Mandatory Guidelines and DOT regulations require that employers submit blind specimens to certified laboratories as part of their drug testing program. Many testing facilities have QA programs that submit blind specimens to the facility as part of their quality practices. Blind specimens provide an excellent means of monitoring all of a facility's procedures. In addition to checking the technical processes of a testing facility, blind samples submitted with broken seals, incomplete CCF, etc., can also challenge the facility's procedures for handling of administrative errors.

The results of blind specimens should be closely monitored, and an investigation should be initiated when the results are inconsistent with target analyte identification or concentration. This investigation should evaluate the supplier and testing facility, identify the source of the inconsistent results, and require corrective actions.

Retests of Non-Negative Specimens

In many programs, the donor of a specimen found to be non-negative may request that an aliquot of the original specimen, in the case of a single specimen collection, or the unopened bottle,

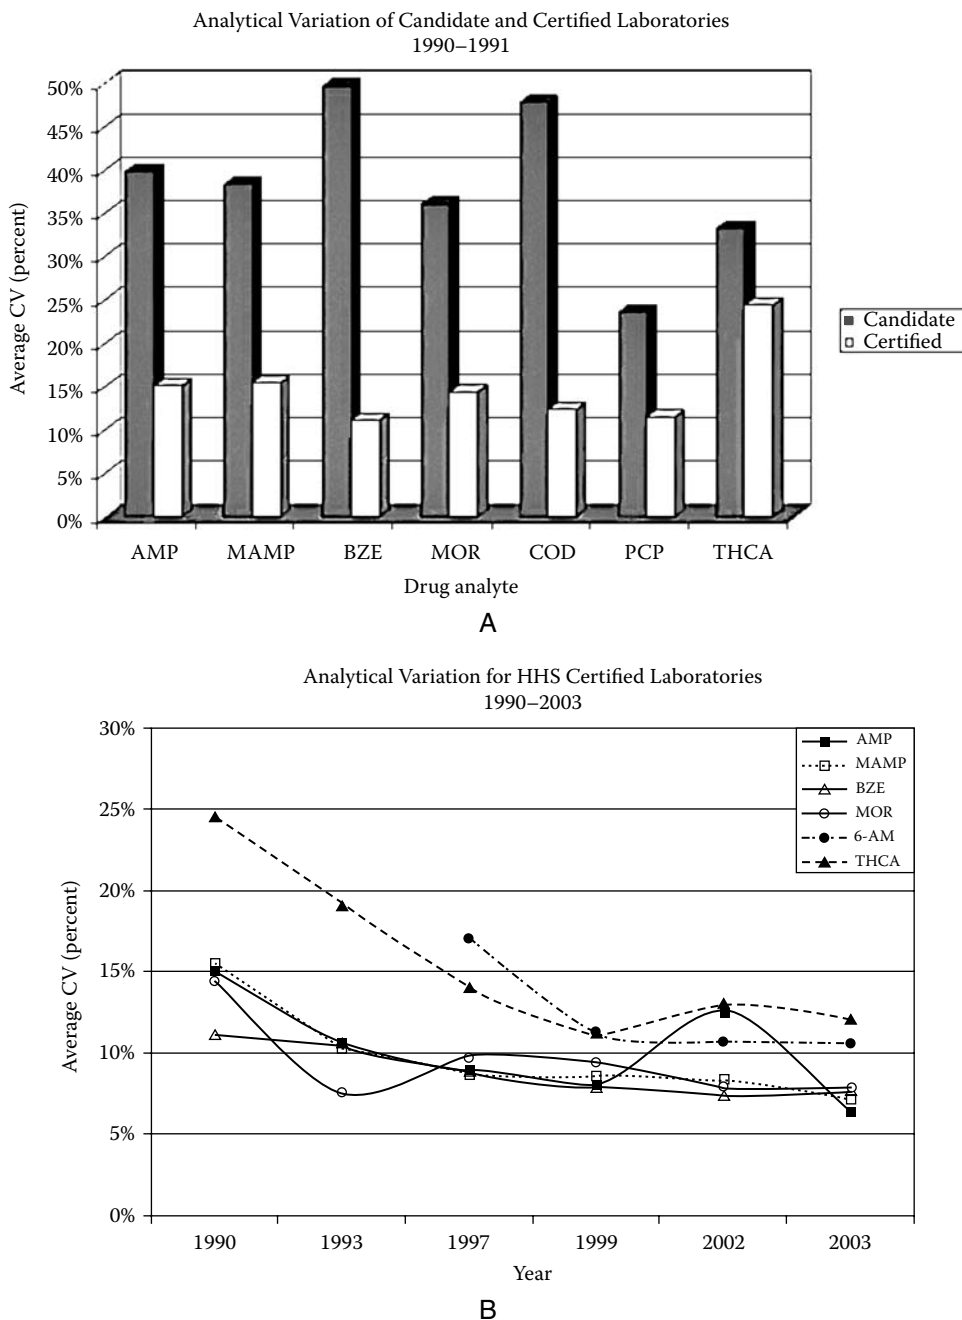

Figure 10.9.1 (A) Comparison of the average CV of GC/MS values reported by NLCP candidate and certified laboratories in 1990–1991 for amphetamine (AMP), methamphetamine (MAMP), benzoylecgonine (BZE), morphine (MOR), codeine (COD), phencyclidine (PCP), and 11-nor-9-carboxy THC (THCA). (B) Average CV for amphetamine (AMP), methamphetamine (MAMP), benzoylecgonine (BZE), morphine (MOR), 6-acetylmorphine (6-AM), and 11-nor-9-carboxy THC (THCA).

in the case of a split specimen collection, be retested. The retest is normally conducted at a testing facility different from the one reporting the non-negative result. Failure of the second testing facility to confirm the original result provides an opportunity to investigate the data from both facilities. Investigations of these incidences most often point to an issue with the collection process, usually the addition of an adulterant or a lack of a proper collection, rather than a testing facility error.

10.9.5 Conclusion

Workplace drug testing programs have become well established over the past 20-plus years. They have grown from a modest beginning in the military to become a program much larger than any imagined. The science and testing methodologies for urine drug testing have been well established. Now, it appears that the structure of workplace testing will change. The pressures from efforts to subvert a urine drug test have generated a need for solutions. Specimen validity testing cannot detect all efforts to suborn drug testing. Civil rights issues associated with observed collections make it clear that they can only be used under specific circumstances. Workplace drug testing using matrices such as hair, oral fluids, and sweat are being offered as a solution. While it would appear that these matrices are less subject to undetectable attempts to circumvent a valid test, there is still discussion within the scientific and legal communities about interpretation of results from these tests and their appropriate use. It is believed that these issues will be clarified and in the future the effectiveness of workplace drug testing will be enhanced as a result of their implementation. However, as a word of caution, this is possible only if the lessons learned about the quality requirements of the urine drug testing system are appropriately applied to the testing of new matrices.

Acknowledgments

The authors express their appreciation to Donna M. Bush, Ph.D., Walter F. Vogl, Ph.D., and Charles Lodico, M.S., of the Division of Workplace Programs, Center for Substance Abuse Prevention, Substance Abuse and Mental Health Services Administration, U.S. Department of Health and Human Services; Richard W. Jenny, Ph.D., of the State of New York Department of Health; and Patricia L. James, B.S., M.A., the State of Florida Agency for Health Care Administration for regulatory insight.

10.10 CURRENT LEGAL ISSUES OF WORKPLACE DRUG TESTING

Theodore F. Shults, J.D., M.S.

Chairman, American Association of Medical Review Officers, Research Triangle Park, North Carolina

Over the 20-year life of modern workplace drug testing, a body of law has been created that is directly related to and directly influences its practice. It is an expansive body, stretching from the constitutional limits on the government's ability to require testing under the Fourth Amendment; it involves a large and expanding matrix of state drug testing laws and legal cases, and travels all the way down to local rules establishing how to introduce drug test results in an unemployment security case.¹ Over this timeframe, fundamental federal laws such as the Americans with Disabilities Act, the Omnibus Transportation Employee Testing Act of 1991, and more recently the Health Insurance Portability and Accountability Act (HIPAA) came into existence. All of these laws affect and shape drug testing practices, the drug testing industry, employment practices, and social policy.

There are a number of legal treatises that deal with employment drug testing and that cover federal and state drug testing laws. This chapter focuses on current key legal issues with a particular perspective of a drug testing service provider and employer. Regardless of the reader's knowledge of and facility with the specific laws of workplace drug testing, the following are broad issues that all employers and providers of drug testing services such as collectors, laboratories, third-party administrators, and medical review officers (MROs) will be dealing with directly in the years ahead.

10.10.1 Liability of Drug Testing

Over these 20 years or so of modern workplace drug testing there have been literally millions of drug tests performed, tens of thousands of positive tests reported, and relatively few lawsuits. There are many reasons for this, but perhaps the most significant is that the analytical procedures are reliable and defensible. Mistakes happen, and mistakes have happened, but there is a very low incidence of error considering the large number of tests performed. Other historical factors contributing to the relatively low level of litigation are that it is often difficult for a donor to bring an action against an employer or a service agent alleging negligence, and the damages of such alleged negligence are often low. One of the great concerns of drug testing has been the fact that often the only evidence of drug use is the laboratory test, and for many donors it is easier to deny illicit drug use and claim the results are a "false positive" than to acquiesce to the results and reality. Thus, there has always been a great deal of potential for litigation, which would cripple drug testing programs.

From the perspective of an employer, the greatest liability is not from drug testing but rather from the damages caused by an impaired employee to a third party. If an employee, acting within the scope of employment, causes injury to customers or to the public after consuming alcohol or drugs, liability may be imputed to the employer under the doctrine of *respondeat superior*. This vicarious liability can occur in commonplace situations, such as an accident caused by an impaired employee driving a company vehicle.² The actual costs of a drug- or alcohol-related accident can be astronomical, e.g., the *Exxon Valdez* environmental catastrophe and damage awards. Employers

involved in hazardous or safety-sensitive work have understandable concern over the drug use, fitness, and qualifications of their employees.

One of the greatest misconceptions in drug testing is that employers who drug-test are at a great risk for lawsuits from employees over the results and adverse employment consequences. That's not true — or at least, it is an overstatement. Certainly, if an employer discriminates against an employee or applicant there are legal consequences, but courts do not want to get into routine hiring and firing decisions, or second-guessing business decisions. Thus, there is the judicial doctrine of *employment-at-will*, which broadly protects employers from direct suits from employees over drug testing.

Essentially, the employment-at-will doctrine stands for the premise that in the absence of an employment contract there is no “temporal” relationship between employer and employee. In other words, the employer–employee relationship can be terminated without notice, and without cause. Since there is no need for a reason to terminate the relationship, it is irrelevant whether the reason for the termination is reasonable, unreasonable, fair, unfair, right or wrong, as long as it is not illegal or against public policy. (An illegal reason is discrimination based on race, age, or sex, retaliation for filing a workers' compensation claim, or termination for certain types of “whistle-blowing.”) Thus, in the absence of any state law to the contrary, employers have a great deal of insulation from lawsuits arising from employment decisions based on drug test results, even if the results are not accurate.

An important distinction is when there is a collective bargaining agreement (CBA). This is a type of employment contract. The key distinction between a CBA and employment-at-will is that an employer cannot terminate a covered employee unless there is a reason, which is usually phrased as “just cause.”³ With unionized employees, the union has a duty to defend its members, and there is a right to a grievance process and arbitration. The employer may have to reinstate a terminated employee following arbitration, and pay back wages, but there are no monetary damages.

From the service provider's perspective, liability issues are more complex. First, there is contractual liability, which is the service provider's responsibility for performing drug testing services appropriately for the client (the employer). For the laboratory, it involves the accurate handling, analysis, and reporting of specimens. For collectors, it is the proper performance of the collection process. For MROs, it is fulfilling the verification process correctly. But this contractual liability exists between the service providers and the client (i.e., the parties to the contract). There have been a few situations where employers have sought damages against a service provider for breach of contract, but this has been relatively rare.

Second, the doctrine of employment-at-will has not been extended to cover service agents, even though they are acting in many cases as the “agent” of an employer. What has historically protected service agents from lawsuits from donors is the fact that the law has not recognized a duty of care existing between the third-party service agent and the donor of a specimen. Historically, the service provider did not owe a “legal duty” to the donor. Thus, a donor who alleged that the specimen was mishandled or was a “false positive” could not bring a negligence claim against the service provider, because an essential element of negligence law is the existence of a legal duty. To be a bit more accurate, the donor *could* bring a suit against the service provider, but it would be quickly dismissed. That has been changing on a state-by-state basis since the mid-1990s. That historical protection or legal insulation is eroding, and has been eliminated in a number of jurisdictions.

A good illustration of how the law looks differently at employers and service providers is the case of *Jane Doe v. SmithKline*. In this 1994 case, the Quaker Oats Company made an offer to an applicant (Jane Doe) for a marketing job. The job offer was contingent on passing a drug test. The drug test was reported to Quaker as positive for a low level of morphine. Apparently there was no MRO verification, and no clinical evidence of abuse. When it learned that the laboratory had identified morphine in the specimen, Quaker simply withdrew the offer.⁴ The applicant, who had quit her job and was in the process of relocating, brought suit against Quaker and the laboratory. Even though Quaker did not use an MRO and withdrew the offer of employment, the court quickly

dismissed Quaker as a defendant under the employment-at-will doctrine. It was not so easy, however, for the lab. The trial court found that it was liable.

The Texas Court of Appeals ruled that, given these facts, a laboratory had a legal duty to warn test subjects of possible influences on results (e.g., poppy seed ingestion). The Texas Supreme Court, however, overruled this decision. The laboratory analysis was correct — there was morphine in the urine. That was what the laboratory was asked to determine, and it did. In the end, a divided court found that the laboratory has no legal duty to warn donors.⁵

The failure to mention poppy seeds to the employer, and the employer's reliance on the test results, may still be a basis for a suit alleging willful and intentional interference with the conditional offer of employment between the employer and employee.

No wrong goes without a right, as plaintiffs' lawyers like to say. Thus, with employment-at-will protecting the employer and with no legal duty attaching to the provider, the donor might not have any legal recourse. Naturally, with drug testing an almost universal employment practice, this insulation was not going to last forever. The law adapts, and it is in that process.

Over the past few years there has been a case-by-case, jurisdiction-by-jurisdiction expansion of what is essentially the scope of legal liability to cover various drug test providers. There is an expanding body of law that allows employees to bring direct actions against laboratories (and theoretically against MROs, third-party administrators, and specimen collectors).

In the first significant case, *Stinson v. Physicians Immediate Care, Limited*, Stinson alleged that the laboratory had been negligent in performing a drug test on him and had reported a false-positive result for cocaine. Stinson alleged that the test result was false or, in the alternative, the report of the test result was false. As is characteristic in this type of case, the allegations were general in nature. The plaintiff alleged the defendant was negligent.

The trial court dismissed Stinson's case on the grounds that a laboratory does not have any legal duty to the donor of the specimen. The appellate court in Illinois, however, reversed this decision and held that a drug testing laboratory owes a duty of reasonable care to persons whose specimens it tests for employers or prospective employers.

The appellate court view was that it is reasonably foreseeable that the tested person will be harmed if the laboratory negligently reports the test results to the employer, that the laboratory is in the best position to guard against injury, and that the laboratory is better able to bear the burden financially than an individual who is wrongly maligned by a false-positive report.

Thus a terminated employee, and presumably a frustrated applicant, has a basis to state a claim against a laboratory by alleging that the laboratory has a duty to the donor to act with reasonable care in collecting, handling, and testing the specimen, and reporting the results accurately. Several appellate decisions have defined the legal responsibility of laboratories.⁶

This expansion of legal duty is not limited to the laboratories. In November 1999, the Wyoming Supreme Court cited the *Stinson* case when it held not only that a collector (and a collection company) owes a duty of care to the donor, but that it also has a duty of care as a consultant, where the collection company recommended a urine alcohol test. (And this duty to the donor essentially extends to all of the service providers.)

The Wyoming case was *Duncan v. Afton, Inc.*⁷ It is another example of a court finding that a drug test provider (in this case, a third-party administrator, a collector, a laboratory, and an MRO) owes a duty of care when collecting, handling, and processing urine specimens for the purpose of performing substance abuse testing. This duty is not only to the employer, but to employees and applicants as well.

All of the above cases deal with the duty of drug and alcohol service providers in regard to allegations of "false-positives" and protecting the donor's interests. A question that has been in the background is whether service providers such as MROs owe a duty to third parties for "false negatives" or "undue delay" in reporting results, or the failure to notify an employer that an employee may be unfit for a safety-sensitive position. In other words, is there exposure for a service

provider who fails to report a “positive” test for whatever reason, and there is a drug-related catastrophic accident?

Such circumstances are rare, but one court case has dealt with such an occurrence. The case, *Turley v. Taylor Clinic*, went to trial in late 2005 in the Aniston, Alabama state court, the first reported case of a drug-related catastrophic accident occurring while the MRO verification process was under way. It is the first case where an MRO has been charged with causing harm to a “third party” — not the donor, but individuals harmed by the donor (a drug-impaired truck driver).

The case illustrates the relatively indefensible position the MRO and the MRO’s employer, Taylor Clinic, were placed in by the failure of the regulations to address a fundamental flaw in drug testing analysis and the intrinsic regulatory conflict between “safety” and the prohibition of removing a presumptive positive donor from safety-sensitive tasks until the verification process is complete.

Methamphetamine exists in two forms called isomers, with significantly different clinical and pharmacological properties. Both forms look identical to a mass spectrometer. The *l* isomer, levmetamfetamine, is found in over-the-counter inhalers like Vicks Inhaler®. The *d* isomer is the form of methamphetamine that acts as a potent CNS stimulant and is the form that is a controlled substance and is abused. The *l* and *d* forms of methamphetamine can be differentiated analytically, but there is no regulatory requirement to do so. Therefore, most laboratories that must compete on price in this mandatory testing program do not do the analysis.

The risk to all MROs is that if they do not order the *d* and *l* test for a methamphetamine positive (in cases where there is no other medical explanation), the MRO is exposed to a future claim from the donor that the results were in fact due to legal use of a nasal inhaler.⁸ The positive methamphetamine donor will allege that the MRO negligently or intentionally failed to order the isomer identification analysis. Thus, under the current regulatory scheme the laboratory’s report of undifferentiated methamphetamine presents MROs with the Hobson’s choice of either verifying a methamphetamine-positive without objective laboratory evidence of whether the drug reported is *d* methamphetamine or *l* levmetamfetamine, or delaying the verification to perform the *d* and *l* testing.

A regulatory conflict exists in addition to this technical deficiency. DOT regulations place a legal duty on MROs to remove donors who present safety risks, and yet also prohibit removal of a donor with a positive test until the result is verified by the MRO.⁹

What happened in the *Turley* case is that the laboratory reported a positive undifferentiated methamphetamine to the MRO. The MRO immediately contacted the truck driver. The truck driver first claimed that the result was due to prescription use of Didrex®, then to Adipex®.¹⁰ He strongly denied use of illegal methamphetamine. The MRO determined that there was no prescription use and ordered the *d* and *l* analysis. The MRO promptly contacted the employer representative as soon as the laboratory analysis came back as *d* methamphetamine.

While the MRO was waiting for the *d* and *l* analysis, the truck driver was seen driving his rig erratically on a major highway. Before the state police could intercept him, the driver exited the highway and ran the stop sign at the end of the exit ramp. A pickup truck collided with the side of his tractor-trailer, resulting in the immediate death of the passenger and the subsequent death of the driver. The truck driver was uninjured.

The police arrested the driver, who could not stay awake. A police-requested blood test for drugs and alcohol was positive for methamphetamine. The truck driver was found to have grossly overextended his time on the road. He had doctored his logbooks and was suffering from fatigue. He pled guilty to vehicular homicide and was given an active jail sentence.

In the discovery process of the wrongful death suits filed against the trucking firm, the plaintiffs’ attorneys discovered that the random DOT drug test for methamphetamine had not been reported to the employer at the time of the accident. To the plaintiffs, this simply looked like negligence. The plaintiffs alleged in their respective complaints that the MRO should have contacted the employer and had the driver removed the moment the lab result came in (although this would have

violated DOT's regulations), and subsequently that the MRO should not have ordered the *d* and *l* isomer test, which caused a delay in reporting the result.¹¹

What the plaintiffs presented at trial were the bad acts of the truck driver and his guilty plea for drug-related vehicular homicide. They pointed out to the jury that DOT regulations refer to the MRO as the "gatekeeper" for the program. This was creatively interpreted to mean the MRO is supposed to protect the public from illegal drug users — specifically, from methamphetamine-crazed truckers. The plaintiffs also read the provisions from Part 40 that state the donor has the "burden of proof" as meaning that if on the first telephone call the donor cannot prove he has an alternative medical explanation, he must be found to be positive and/or removed from service.

It mattered little that these were fundamental misinterpretations of the regulations. It did not seem to matter that the MRO role is also to protect individuals who are not illegal drug users from being falsely accused or losing employment because they use an over-the-counter inhaler. It was quite simple for the plaintiffs: local fellows are dead, an out-of-town doctor failed to report the results — bad outcome, bad MRO.

These issues could have been addressed. However, the defense was essentially forced to settle this case by following the informal guidance (or as it was described, the bombshell) that was dropped by DOT's Office of Drug and Alcohol Policy and Compliance (ODAPC). The defense counsel for Taylor Clinic asked ODAPC its view on the actions of the MRO and presented the office with a "hypothetical" synopsis of the facts. The defense counsel was surprised to learn from ODAPC that:

... the MRO had no compelling medical reason to order the *d,l* isomer test and delay reporting. The donor offered no medication or explanation in the hypothetical that gave a reason for delaying the final verification decision waiting for that particular additional test.

The new concept of requiring a *compelling medical reason* to order a *d* and *l* test is without any regulatory basis and is in frank conflict with the guidance DOT has given for over a decade.

It also raises the question of whether an MRO, in the absence of a compelling medical reason, should delay reporting of *any* positive results where the purported explanation is unlikely. For example, it is common for a donor to claim that he or she is positive for cocaine because his or her dentist used cocaine in a recent procedure. It is generally understood in the MRO community, the general medical community, and the dental community that cocaine is not used in routine dental procedures in the U.S. The standard of practice has been, however, for the MRO to give the donor some reasonable amount of time to get information from the dentist. Some MROs even contact the dentist directly to verify the information. If there is a drug-related accident or injury while this aspect of the verification process is under way, can it now be alleged that the MRO was negligent because there was *no compelling medical reason* to verify the donor's claim? DOT has certainly opened the door for such allegations.

ODAPC further exacerbated its guidance to Taylor Clinic in respect to verification of methamphetamine by subsequently proposing that MROs go ahead and report positive methamphetamine results without the *d* and *l* analysis. The MRO is then free to decide whether to order the additional test. In the event the *d* and *l* results are reported back as all *l* isomer, the MRO can issue a "revised" report. This sounds reasonable, except that in most cases the donor will have already been fired, and most employers who are not governed by collective bargaining agreements will be under no legal obligation to rehire them. It is doubtful that this "guidance" is even constitutional, as it is simply an unreasonable rule with unreasonable results. At the time of this writing, these concerns have been expressed to DOT without satisfactory response.

Turley v. Taylor Clinic is the worst-case scenario for an MRO and for the government. It all stems from the failure of the HHS Mandatory Guidelines to require laboratories to identify which form of methamphetamine they are reporting. If the trend is toward holding the service provider

liable for the shortcomings of policy and regulatory schizophrenia, MRO verification of DOT results will begin to present unacceptable levels of risk. Some legislative relief would be appropriate.

10.10.2 Specimen Validity: Managing the Integrity of Specimens and the Question of Federal Preemption

Workplace drug testing has historically been based on the analysis of urine specimens. There are many advantages to using urine. There is sufficient quantity, it is easy for a laboratory to handle and manipulate the specimen, urine is mostly water, and the physiologic processes and kidneys provide a first pass at concentrating the metabolites and drugs of interest in the urine. The development of high-speed automated immunoassay instruments in the 1980s facilitated the ability to quickly and effectively screen urine specimens and made large-scale urinalysis programs practical. Urine gives a 2- to 3-day window of detection using typical workplace drug testing cutoff levels.

The disadvantage of urine is, frankly, that it is urine. Urine collection involves a personal and private process that requires a reasonable degree of privacy. A legal (and social) constraint of urinalysis testing is the premise that in the absence of individualized suspicion of adulteration or other subterfuge of the collection process, it is unreasonable to witness or directly observe the production of a urine specimen.¹² This “reasonable” degree of privacy in the collection process has provided a reasonable opportunity for a drug user to adulterate, substitute, or otherwise attempt to undermine the drug testing process, and many have. Adulteration and substitution have challenged the integrity, technology, and economics of urine drug testing. The very principles and legal foundation of drug testing have been challenged by the adulteration industry and their willing accomplices: drug users who have no interest in changing their behavior.

In 2004, HHS implemented a technical strategy that required certified laboratories to screen all specimens received from federal agencies for the presence of oxidants, check the pH, and determine the level of creatinine.¹³ The new standard is known as the specimen validity testing (SVT) rule. It establishes a technical protocol that provides a level of screening and confirmation for adulterants and the identification of substituted specimens equivalent to the identification of prohibited drugs and metabolites.

The rule was framed as the ultimate solution for the war on adulterants. However, in developing its SVT rule, HHS made a fundamental policy decision to require only a generic screening for adulterants, and not to require any laboratory to have a confirmation procedure for the screen. A survey of laboratories in 2005 indicated that the certified laboratories have essentially abandoned the process of adulterant confirmation.¹⁴ One presumes that the extent of the laboratory retreat from this area was unanticipated, but the consequence has been the precipitous drop in the number of adulterated specimen reports.

A specimen that meets the screening criteria for a tampered or suspect specimen is then reported as an “invalid” result. Following the implementation of the SVT rule, all adulterated specimens became invalids. These “invalid” results trigger requirements for the MRO to have discussions with the laboratory, call the donor to discuss the results, and in most every case call the donor back for an observed recollection. In addition, now the MRO must even “verify” that the observed collection was indeed observed.

This approach begs the question: What are the results of these second observed collections? How many are positive? No systematic data has been released to support the fundamental premise of the SVT rule. Is the return visit of the donor with an invalid any better than requiring a second drug test of anyone for no reason? Under this rule, the mandatory recollection of specimens under observed conditions is not productive.

Unfortunately, the HHS specimen validity testing rule has been implemented and serves as a standard and template for testing federal agency employees. It has become the *de facto* standard, being authorized under DOT and NRC for regulated industry. In late 2005, DOT formally proposed

adopting these rules without modification.¹⁵ However, DOT and NRC are still evaluating the merits of the overall approach, and may ultimately decide not to follow this protocol.

A recurring pattern of specimen validity testing has been that when laboratories begin to test for a particular adulterant, such testing has a profound impact on the use of the identified adulterant. In the 1990s glutaraldehyde was one of the more common urine adulterants. Its use dropped off sharply and in a relatively short period of time after the laboratories began to identify the compound. Unfortunately, this lesson has not been incorporated into the HHS SVT rule. There are now no more confirmed adulterated test results, only invalids.

Current thinking is that alternative tests such as oral fluid, sweat patches, and even hair testing provide a better specimen because the collection is essentially one that is observed. But the adulteration industry sees these “*alternative*” specimens merely as new markets and opportunities ahead. Adulteration products are already available to “clean toxins” out of hair. One can foresee a line of products to “detoxify” the mouth and breath and to purify sweat. Like so many products in this genre, the product does not have to work to be successfully sold in this market.

To date, the legal issues of specimen validity testing have not involved the question of whether it is appropriate to test for adulterants or for substitution. The focus has been on the integrity of the analysis and the validity of the cutoff levels.

Although laboratories are not actually performing confirmation testing of adulterants, they are reporting creatinine and specific gravity results. The creatinine cutoff level for a substituted specimen was initially established by HHS at 5 ng/ml. This was, however, found to be high enough for some individuals to achieve. In other words, it was not medically or physiologically impossible to produce a “substituted” specimen at or around this level. Although a donor could challenge the substituted results and engage what was called a “referral physician” and demonstrate their ability to produce creatinine at such low levels, it was a burdensome process.

In February 2003, a colloquium funded by Congress and hosted by the FAA Civil Aerospace Medical Institute (CAMI) specifically convened to assess the soundness of the specimen validity rules in effect at that time.¹⁶ One result of the research and findings of this colloquium was the decision to lower the creatinine cutoff level for substituted specimens.

The change from 5 ng/ml creatinine to <2.0 ng/ml was made officially by DOT on May 28, 2003. DOT also directed that specimens that had been previously reported as substituted and had a creatinine between 5 and 2 were to be canceled. They are now reported as “dilute” and require a subsequent collection under direct observation.

A separate but related concern to determining the appropriate physiological cutoff values for creatinine and specific gravity is the issue of how accurately these can be measured. A lot was learned the hard way. In the early days of testing some of the analytical instruments designed for measuring creatinine levels had a feature of truncating results, or rounding down to the lower integer. This feature was buried in the software and no one really cared about the decimal place, until substitution became an issue. Dropping the fractional number turned out to have significant consequences.

The case that received the most attention in respect to truncating creatinine results was *Ishikawa v. Delta Air Lines, and LabOne, Inc.* On July 3, 2001, a federal district court jury in Portland, Oregon, found LabOne negligent under the state negligence law in the laboratory analysis of Yasuko Ishikawa’s drug test. LabOne had reported Ms. Ishikawa’s specimen as substituted to her employer, Delta Air Lines, and Delta had fired Ms. Ishikawa, who worked as a flight attendant. Her dismissal was based on Delta’s policy to terminate employees who have been reported as having substituted or adulterated specimens. The laboratory found itself in the difficult position of not being able to prove conclusively that Ms. Ishikawa’s urine did in fact meet the existing definition of a substituted specimen, primarily because of the software truncation of creatinine results. The laboratory was also placed in the difficult position of defending a federal standard for creatinine levels that was subsequently lowered.

In the end, Ms. Ishikawa was awarded \$400,000 in compensatory damages. This verdict was appealed on the grounds that federal law, in particular the Federal Omnibus Employee Testing Act, which is the current statutory authority for the DOT regulations, “preempts” state law, including negligence law. The trial court did not accept that argument, and the case was appealed to the Ninth Circuit Court of Appeals. The Ninth Circuit took the opposite view and noted that if anything, Part 40 *preserved* the donor’s right to sue. The court noted that the DOT regulations expressly provide: “[t]he employee may not be required to waive liability with respect to negligence on the part of any person participating in the collection, handling, or analysis of the specimen.”^{17,18}

The court deduced that since negligence is a state common law tort, it would make no sense for the DOT regulation to prohibit requiring the employee to waive negligence claims if those claims were preempted and could not be made. This regulation prohibiting required waivers of negligence claims implies that such claims exist and are not preempted.

On November 30, 2004, the Eighth Circuit followed this decision in *Chapman v. LabOne* and *Howell v. LabOne*. These two cases were consolidated on appeal. In both cases the federal district court judges ruled that the state negligence action against the laboratory was preempted. The district court in Iowa dismissed the *Chapman* case on the ground that the common law claims were preempted by the Federal Railroad Safety Act (FRSA), as amended by the Federal Omnibus Transportation Employee Testing Act of 1991 (FOTETA), and the Railway Labor Act (RLA). The district court in Nebraska ruled that removal of the *Howell* case was proper based on the doctrine of “complete preemption” under the FRSA and the FOTETA, and then dismissed the case on the ground that the FOTETA provided no private right of action.

The Eighth Circuit reversed both of these cases and noted:

We agree with the Ninth Circuit that “[n]egligence is a state common law tort, and it would make no sense for the regulation to prohibit requiring the employee to waive negligence claims if those claims were preempted and could not be made.”

This appears to be the current majority view, which essentially means service agents (not just laboratories) performing drug testing under the DOT program will be subject to state negligence law in respect to their work, in jurisdictions that have expanded the “duty of care” to donors. The legacy of the litigation surrounding specimen validity issues has resulted in a more rugged technological approach and numerous additional safeguards for specimen validity testing. It may also be a turning point in how the industry views the litigation risks of this endeavor.

10.10.3 2005 Congressional Interest in Adulteration and Substitution

On May 17, 2005, the House Energy and Commerce Oversight and Investigations Subcommittee held a public hearing to investigate the issue of the subversion of federal drug testing by adulteration and substitution. There had been growing interest in getting Congress involved in this problem, specifically seeking federal legislation to help curb the marketing and use of devices and chemicals designed to defeat drug tests.

The hearing came coincidentally on the heels of a widely covered story of Minnesota Vikings running back Onterio Smith, who was detained by airport security who were curious about the freeze-dried urine in his carry-on luggage. No doubt they were also curious about the plastic prosthetic device that was also present. What Mr. Smith had was *The Whizzinator*, which has been on the market for a number of years. The Whizzinator consists of a prosthetic penis that will deliver a liquid at about 98.6°F. It is now sold with freeze-dried urine.

Thus, the Whizzinator became the media breakout product for the adulteration and substitution industry. But the Whizzinator is just one of approximately 400 products available today to defeat

drug screening tests, according to the report by the U.S. Government Accountability Office (GAO) released at the hearing.

The sheer number of these products, and the ease with which they are marketed and distributed through the Internet, present formidable obstacles to the integrity of the drug testing process.¹⁹

The GAO report was released as three major manufacturers and sellers of the adulterants and devices pleaded the Fifth Amendment, declining to answer questions at a hearing after receiving subpoenas from the House Energy and Commerce Oversight and Investigations Subcommittee.

At this time a bill has been introduced in the House of Representatives titled: The Drug Testing Integrity Act of 2005. The purpose of the bill is "To prohibit the manufacture, marketing, sale, or shipment in interstate commerce of products designed to assist in defrauding a drug test." It is a short bill that focuses on the manufacturers and distributors of these products, which are riper targets than users. Such federal legislation will not eliminate the problems of adulteration and substitution, but it will certainly help.

10.10.4 Expanding Technology: The Opportunity and Challenge of Hair, Oral Fluid, and Sweat Testing

There has been long-standing interest and research in testing other biological specimens, such as saliva (now referred to more accurately as oral fluid), hair, and sweat. One generic advantage of all these methods is that collection of the specimens can be witnessed by a collector. A witnessed collection greatly reduces the opportunity for adulteration or substitution. There are other advantages and disadvantages of these methods, and a somewhat new legal frontier is ahead.

In April 2004, HHS published a proposed rule to amend the current Mandatory Guidelines for Federal Workplace Drug Testing.²⁰ The amendment would have expanded federally mandated drug testing to include the collection and testing of hair, oral fluids, and sweat. It also would have expanded urine testing to include on-site testing, decentralized screening of urine, the testing of designer drugs, and lower cutoffs for amphetamine and cocaine.

Oral fluid is relatively easy to obtain from a donor. In what is referred to as laboratory-based oral fluid testing, a stick with an absorbent pad is placed in the mouth for a short time.²¹ In one system, the device is sent to the laboratory for screening and confirmation. There is more and more evidence that oral fluids perform equally as well as current urine testing in terms of prevalence rates of positive drug tests. It is a very promising technology that is particularly attractive not only to employers, but also to school districts interested in drug testing students. On the other hand, there is some concern that the method has a relatively shorter detection time for marijuana use and paradoxically is more susceptible to "passive" or secondhand smoke.

Hair testing has been a controversial area of drug testing for more than a decade. It is clear that drugs and metabolites can be sequestered in the matrix of the hair and may be identified years after use. In workplace programs, only a relatively short section from the scalp is tested. This practice is to correlate the detection window to the past 90 days of hair growth, which will fall within the bounds of the "current use" definition of the Americans with Disabilities Act. One issue that remains somewhat unresolved is how well the laboratories can distinguish use of the parent drug from environmental contamination. Some laboratories are quite adamant that this is not an issue; other experts are not so sure.

Another complexity of hair testing is that there is large body of evidence that the sequestered amount of some drugs such as THC and cocaine is proportional to the darkness of hair. There is a good correlation of the amount of drug in hair and the amount of melanin. There is a somewhat charged debate in the toxicology community, and moving into the legal community, as to the significance of this color bias in respect to its possible disparate impact on African-Americans and Hispanics.

The use of sweat is not common in workplace drug testing programs because it involves the adherence of a sweat patch to donors for a period of at least a week. Its use is almost exclusively in monitoring treatment and abstinence.

The HHS proposed rule summarized 8 years of work by industry working groups and framed many of the critical issues. It was subject to public comment and was extensively critiqued as raising as many questions as answers. The 283 formal comments raised 2000 separate issues that needed to be addressed. In 2006, the Office of Management and Budget (OMB) announced on its list of 2006 completed rulemaking that these proposed amendments have been withdrawn.

Regardless of this misadventure, much was learned. These alternative technologies will continue to develop and grow in the private sector. Private employers are still faced with the challenge of assessing the technical and practical merits of each alternative technology.

Conceptually, the alternative biological specimens provide different types of information about drug use and drug exposure. An individual's current mental and physical status and recent use may be best assessed in terms of oral fluid testing results. Past history and pattern of use may be best revealed with hair. It is unlikely that a hair test would be used for a post-accident test, simply because hair tests do not typically reflect drug use in the past few days, and there is no peer-reviewed data showing a correlation between hair concentration and behavioral effects. Similarly, the use of an oral fluid test, which provides a relatively narrow window of detection of recent drug use, would be of less value than urine in assessing abstinence for the purposes of a return-to-duty test. Urine testing has been used for all types of drug tests: random, pre-employment, post-accident, for-cause testing, and return-to-duty. It is unlikely that any of the alternative tests would have such broad application.

In the years ahead, the courts will be dealing with all of these technologies in a variety of circumstances. In general, the legal issues and litigation will be similar to what has been seen with urine testing. Is the test accurate? Was the test, collection, or interpretation done correctly? Does the employer have the right to use these tests? Do the tests violate existing state privacy or drug testing law? Do the tests and the employer's policy violate the Americans with Disabilities Act? Do the tests discriminate against a protected class?

To the degree that alternative testing methods mimic the technical safeguards in urine testing, such as using approved and accepted screening and confirmation methods and having MRO verification, the legal cases should follow the same results that urine testing has produced.

The courts (and perhaps legislatures) may also be dealing with a relatively new issue that did not exist in a one-test universe of urinalysis. The new issue is whether the selection of a particular method is "fair." Is it fair to screen some employees with urine testing and others with hair? Or is it fair to have oral fluid testing for some post-accident testing and urine for others? Does the less-rigorous standard open the door for charging that an employer is not doing an adequate job of screening employees?

Employees have a strong sentiment that testing should be fair, although their definition of "fair" may not necessarily be rational. For example, employees may feel that for drug testing to be fair everyone has to be tested at the same time, or that employers have an obligation to provide assistance and/or treatment for substance abuse. Employers also have an interest in projecting fairness. The reality is, however, that life is not fair, and there is limited legal recourse for "fairness" for employees. Here is where state legislatures have stepped in — for better or worse, depending on one's perspective.

At the federal and state level, a more rigorous constitutional test is required when a government agency performs the tests or requires an employer to test as part of a regulation or law. It is premature to speculate on the legal significance of "fairness" in the federal program, other than to say that the U.S. Constitution requires reasonableness. At some point, *fair* and *reasonable* intersect.

The constitutional requirement of governmentally mandated testing also requires a showing of compelling governmental reason for testing by one of these novel methods, and that the testing is

minimally invasive. If these tests are ever added to the federal program and the legal challenges are resolved, employers will have a firm basis for decision making.

With no federal standard in place for testing these biological specimens, all of these methods are currently being used by employers in the private sector in a trial-and-error approach. With an understanding of the technical limitations and weaknesses of each method and an appreciation of the legal risks in a particular employment environment, employers can make sound decisions and enhance their programs with the proper use of these technologies.

10.10.5 Managing Prescription Drugs: The Use/Abuse, Treatment/Risk Analysis

The focus of workplace drug testing has been on “illegal” drug use and alcohol misuse and abuse. The primary legal justification for focusing the government’s drug testing program on illegal drugs has been in large part the concern for public safety. Private employers share this concern and have additional justifications for their interest and involvement in drug testing. What has become evident is that safety, performance, integrity, and addiction are also being significantly affected by the abuse of prescription drugs.

Workplace drug testing programs do not directly address the safety and performance issues of prescription drug abuse. The essence of the federal model for workplace drug testing programs is to establish a policy that prohibits the use of “illegal” drugs, tests for the presence of these drugs, confirms the presence, and then determines through a confidential dialogue with an MRO whether there is an “alternative medical explanation” for the presence of that drug or metabolite. *Alternative medical explanation* essentially means that the drug was obtained legally by means of direct administration by a physician, such as topical cocaine to a broken nose, or by prescription (e.g., codeine). Once it has been established that the drug was obtained legally, the results are reported as negative.

The existing model does not directly address the issue of whether prescription use is appropriate, such as the prescription for Marinol® for complaints like “nervousness,” or the donor’s multiple prescriptions for stimulants, or the donor’s inappropriate dosing of codeine, or even the use of an old prescription.

The DOT and NRC programs have provisions for the MRO to determine whether a safety issue exists and to report it to the employer or to make an assessment. In the DOT program, this happens when the problem comes to the attention of the MRO, usually inadvertently. Many nonregulated employers are following this approach, and expanding on it by expanding the menu of drugs being tested. Typically the expanded drugs include the synthetic narcotics and benzodiazepines.

The challenge for employers (and society) is how to effectively manage the appropriate use of drugs that have abuse potential and present safety and productivity problems. Although the two largest categories of drugs of concern are historically the synthetic narcotics and the benzodiazepines, there are others.

There are a few cases where employers have taken some independent actions. In an interesting case, a large trucking firm automatically disqualified all applicants who reported that they were taking drugs that were on a list compiled by the firm’s safety director. Any drug that was identified in the *Physician’s Desk Reference* as requiring a warning about driving was added to the list. The court did not find this to be a violation of the Americans with Disabilities Act.

Testing is, however, only a part of the management of prescription drugs. Employers who are involved in safety-sensitive work have to develop comprehensive policies and procedures that require the disclosure of prescription drugs to a designated medical representative, who then can make an independent judgment in conjunction with the treating physician as to the performance of safety-sensitive functions. The disclosure of prescription drug use can be framed in such a way as not to violate the Americans with Disabilities Act, by avoiding adverse employment action and focusing on the safety issues. These procedures are best justified in clearly safety-sensitive environments, and some degree of employee education is also required. (There need not be any requirement to disclose drug use unless the drug has an effect on performance.)

A related issue has been the growing use of the Internet, not only for filling legitimate prescriptions, but also for obtaining questionable prescriptions for controlled substances. A number of MROs have noted that donors who have tested positive for amphetamines claim to have a prescription and to have obtained the amphetamine from an Internet pharmacy. The issue is not that the prescription was filled by an Internet pharmacy, but rather that the prescription itself was issued by a physician over the Internet, related to or referred from the pharmacy site.

The DEA position is that a prerequisite requirement for the issue of a prescription for a controlled substance is a doctor–patient relationship, and that such a relationship must be based on a face-to-face meeting. Unfortunately, in some states a doctor–patient relationship can be created over the telephone, and telemedicine is only expanding the exception to the face-to-face rule. It is these states that license Internet pharmacies, however, not the DEA.

The problem of Internet prescription writing is not unmanageable for the MRO. Under the DOT regulations the donor has the obligation (burden) to present sufficient evidence to the MRO that his or her drug use that resulted in a confirmed positive laboratory result was obtained by prescription. In the typical Internet case, the donor often has a hard time determining who the prescribing doctor is and establishing that he or she is a licensed physician, or establishing that the drug was dispensed in accordance with federal and state laws. It is highly unlikely that, if there is a physician involved, the physician can establish to whom he or she wrote the prescription. The Internet is anonymous. In these cases the donor cannot meet the minimal requirement of identifying the physician, and the physician cannot establish for whom the prescription was written. In the absence of a face-to-face meeting and any meaningful diagnosis, these cases are typically reported to employers as presenting a safety problem.

10.10.6 Medical Marijuana

Medical marijuana is not a prescription drug, but its use has been decriminalized in 11 states. Most of the state medical marijuana acts list the medical conditions for which the drug can be used and require the “recommendation” of a physician. Many states also have formal patient registries and other conditions of use. In the U.S., the federal government and the states share jurisdiction in respect to the control of legal and illegal drugs. There is usually symmetry in this dual jurisdictional approach, but not always, as seen in the controversy over medical marijuana.

Federal policy has been consistent in prohibiting MROs from accepting medical marijuana as a valid explanation for a positive THC test. Synthetic versions of THC (such as Marinol®, a Schedule III controlled drug) are, however, acceptable. The challenge has been for employers operating in states with medical marijuana acts to develop policies that are legally enforceable. Much of the legal uncertainty has been resolved by the courts.

The most significant court decision in this area is the well-publicized case of *Raich v. Ashcroft*. In *Raich*, the users and growers of marijuana for medical purposes under the California Compassionate Use Act sought a declaration that the Federal Controlled Substances Act (CSA) was unconstitutional as applied to them, in that this federal law is based on the commerce clause, and that growing marijuana legally for one’s own use is not “commerce.” The plaintiffs prevailed on this argument, which was then appealed to the Supreme Court.

In November 2004, the U.S. Supreme Court heard oral arguments in *Raich v. Ashcroft* (retitled *Raich v. Gonzales*). On June 14, 2005, the Supreme Court released its decision. The Court upheld the federal government’s constitutional authority to prosecute the possession, sale, and manufacture of marijuana, regardless of conflicting state law.²²

The government’s brief in the *Raich* case stated:

The “home-grown” manufacturing, free distribution, and possession of controlled substances, whether for recreational or purported medicinal purposes, also pose an appreciable risk of diversion to others for further drug use or distribution, a result that further swells the illicit market. Local users may

ultimately sell or divert the drug to others (for instance, should their production yield exceed their purported needs or should additional funds be required to finance their drug production or other activities).²³

Justice Souter noted in oral arguments that there could be 100,000 medical marijuana patients just in California, based on the number of cancer/chemo patients. No one disagreed. He noted that carving out an exception for patients in the absence of any other control is *de facto* decontrol. Justice Souter's observation is correct, but the decision in this case, while maintaining the *status quo*, did not end the matter.

The Supreme Court decision did make it easier for employers in California and other states with medical marijuana acts to prohibit the use of native marijuana in any form, particularly for safety-sensitive jobs. But *Raich* did not deal directly with employment issues, and many employers remained worried over possible claims of disability, discrimination or wrongful termination. Those claims could quite easily be tried in a sympathetic state court with a sympathetic jury and a sympathetic sick employee using medical marijuana.

Employers' concerns over disability claims have been greatly reduced with a significant decision by the Oregon Supreme Court. That watershed case is *Washburn v. Columbia Forest Products*, which was decided in May 2006. The issue that was before the Oregon Supreme Court was whether the Oregon State Disabilities Act (which tracks with the Americans with Disabilities Act) requires an employer to make a disability-related accommodation for an employee who uses marijuana for medical purposes.

The plaintiff, Robert Washburn, was an employee of Columbia Forest Products, Inc. He was also a medical marijuana recipient who regularly used the drug before going to bed to counteract leg spasms that otherwise would keep him awake. After he tested positive for marijuana use, Columbia terminated his employment. Washburn brought action against Columbia, alleging a violation of state prohibitions against disability-related discrimination in the workplace. The trial court granted summary judgment for Columbia, holding, in part, that Washburn was not "disabled" under the pertinent Oregon statutes. The court of appeals disagreed with that conclusion and held that Columbia's summary judgment motion should not have been granted.²⁴

Upon review, the Oregon Supreme Court concluded that Washburn was not "disabled." The court followed the U.S. Supreme Court's line of reasoning in previous cases that hold if a drug or corrective action corrects or mitigates the disability, the person is not "disabled" and there is no requirement to make any further accommodation.²⁵ Setting aside the somewhat circular reasoning of the courts, this decision provides solace to employers in states with medical marijuana laws.²⁶

A separate concurring opinion in the case makes the more salient point that, although a state may choose to exempt medical marijuana users from the reach of state criminal law, it is not reasonable to require an employer to accommodate what federal law specifically prohibits.

Although there are employers in jurisdictions where medical marijuana has been excluded from state criminal law sanctions who accept medical marijuana as a legitimate excuse, these employers are making the accommodations more on the basis of employer–employee relations and community standards.

For MROs, the claim of medical marijuana is common in states with medical marijuana laws. MROs recognize that legitimate cases are mixed in with a significant number of bogus claims. Recommendations from physicians to use medical marijuana are not hard to obtain.

Effective management of medical marijuana in non-regulated, non-safety-sensitive employment situations requires some degree of collaboration between MROs and employers, and the establishment of sound employer policies on what is and what is not acceptable.

10.10.7 Screen-Only Drug Testing

On-site drug testing technology has progressed and diversified to the point where it appears that a broader definition of the term "on-site" is needed. On-site testing initially referred to bench-

top automated immunoassay devices used outside of a formal laboratory setting. Over time, as immunoassay methods progressed, instrumental measurement of the immunoassay reaction could be replaced by visual inspection. Immunoassay impregnated on plastic cards became the new “on-site” technology, and the term “non-instrumented on-site testing” was adopted. A variety of different designs exists, from bottles with the immunoassay integrated into the side, to cards that are simply dipped into a urine specimen. Most of the technology is designed to produce a line when the specimen is negative for the specified drug, and the absence of a line indicates a “presumptive” positive test. Most current strip technology performs equally to laboratory screening in identifying negative tests. But like the laboratory-based immunoassay screening, it is not 100% conclusive of the presence of a prohibited drug.

Further, the distinction between instrumented and non-instrumented immunoassay on-site testing is also dissolving. Handheld instrumental devices are in development that will provide an “on-site” analysis of oral fluids and urine. Visual interpretation of a line or no line will be replaced by an automatic report or a simple display. Another innovation is the integration of an on-site instrument that objectively reads the immunoassay results and transmits the results over the Internet to a centralized facility. The computer at the central facility analyzes the results according to a software program and essentially determines whether the specimen should be sent to a laboratory for further testing (either as a non-negative or a random quality control). The final results are then reported to an MRO. This type of approach is a hybrid of centralized laboratory management and local collection and screening. The first such product, called *eScreen*, is already being marketed.

The open question in the utilization of inexpensive immunoassays is to what degree all of the safeguards of training, quality control, and technical management, which are required and used in a certified forensic drug testing laboratory, are applicable to on-site testing, and whether they are necessary.

It should go without saying that existing confirmatory testing requirements will continue to be required in the event that on-site technology becomes incorporated into federally mandated drug testing programs. Confirmatory testing is one of the essential constitutional requirements of federally mandated testing. In workplace drug testing, confirmatory testing has become synonymous with GC/MS technology. But in a broader sense, confirmatory tests can be conducted with LC/MS or MS/MS or comparable instrumentation. The essential element of confirmatory testing is the independent definitive nature of the analysis. It is the true technical foundation upon which sound decisions affecting employment can be made.

All manufacturers and distributors of on-site products are in the chorus recommending GC/MS confirmation and MRO review. However, it is not a foregone conclusion that either of these safeguards will be automatically included in private sector workplace drug testing programs, in the absence of a state law requiring them. Most employers do not have a legal duty or mandate to require confirmation testing, and the economics and apparent simplicity of screen-only results are seductive.

The employment-at-will doctrine is a pillar of labor and employment law in the U.S. The doctrine essentially states that either party to an employment relationship, the employer or the employee, can terminate the relationship for any reason, or for no reason. Thus, it is argued that an employer may terminate an employee based on a screen-only result, but it is an ill-advised practice. First, it is highly unlikely that a screen-only result will be persuasive in any employment proceeding, whether it is an unemployment security hearing, labor arbitration, or a workers' compensation hearing. Further, the employer's publication of a screen-only result to another employer may raise the issue of defamation. This is because for all practical purposes, 99% accuracy is simply not good enough. All screen-positives claim to be that 1%, and the law allows them to make that claim.

A collateral rule to the employment-at-will doctrine is that an employer is free to hire or not to hire applicants based on the employer's assessments, as long as the hiring criteria and decisions are not discriminatory in nature. Thus for many employers the use of a screening device for applicants that produces false-positives does not appear to present any significant legal repercussions.

There is essentially no “right” to any job. Applicant screening is the target market for many on-site testing devices. It is a very large market, and many employers do not perceive a need for confirmatory testing or for MROs. In the absence of any state prohibition against screen-only testing of applicants, the argument can be made that the employer who does screen-only testing could run afoul of the Americans with Disabilities Act. Applicants who have been denied a job without confirmation testing may bring an action claiming that they were discriminated against because the employer thought that they were illegal drug users and have a disability, and they do not use illegal drugs and do not have a disability. Although this argument may technically be true, it is not a strong discouragement of screen-only practices.

The broader danger of widespread screen-only practices will be the undermining of the public’s acceptance of drug testing. The unwritten social pact is that drug testing is accurate and reliable, and that there will be no adverse impact on an individual who is not currently engaging in illegal drug use.

The open question is whether the incident rate of litigation will continue to remain low, or whether the industry will be faced with increased risk exposure and legal costs. It will not take too many cases for service providers to withdraw from this market.

NOTES

1. The “rules” of workplace drug testing vary considerably and are dependent on such things as who is being tested, why they are being tested, who is doing the testing, and where the test is being collected and performed. An employer in Maine must have a comprehensive program with all the safeguards in place approved by the state before testing, while the same employer in a state with no drug testing law can screen an applicant’s urine with an unapproved on-site immunoassay device with impunity. There has been an ongoing process of state legislation that has generated hundreds of statutes that prescribe what is allowed in a particular state and what is not allowed. Today it is nearly impossible for a company to have a uniform drug and alcohol policy and procedure that can be rolled out nationally. This will be a continuing challenge as employers begin to adopt other testing methods.
2. See, e.g., *B & F Eng’g, Inc. v. Cotroneo*, 309 Ark. 175, 830 S.W.2d 835 (1992). The court noted that the negligence of impaired transportation workers, such as flight mechanics, bus drivers, or railroad switchmen, can cost an employer millions. *Mulroy v. Olberding*, 29 Kan. App. 2d 757, 30 P.3d 1050 (2001). But see *Beckendorf v. Simmons*, 539 S.W.2d 31 (Tenn. 1976). When the employer had repeatedly forbidden the employee to drive the vehicle, there was no liability.
3. In most collective bargaining agreements, the employer has agreed to provide assistance and a SAP evaluation and return-to-duty requirements for transgressions of the substance abuse policy.
4. The amount of morphine in the specimen was around 600 ng/ml, which is quite consistent with poppy seed ingestion.
5. *SmithKline Beecham Corp. v. Doe*. 903 S.W.2d 347 (Tex. 1995).
6. The following are the cases that reached the appellate level. Drug testing laboratory owes persons tested a duty to perform its services with reasonable care: *Willis v. Roche Biomedical Lab.*, 21 F.3d 1368, 1372-1375 (5th Cir. 1994); *Stinson v. Physicians Immediate Care, Ltd.*, 269 Ill. App.3d 659, 207 Ill. Dec. 96, 646 N.E.2d 930, 932-934 (1995). Laboratory owes prospective employee a duty not to contaminate sample and report a false result: *Nehrenz v. Dunn*, 593 So.2d 915, 917-918 (La.Ct.App. 1992). Laboratory owes employee a duty to perform test in a competent manner: *Elliott v. Laboratory Specialists*, 588 So.2d 175, 176 (La.Ct.App. 1991); writ denied, 592 So.2d 415 (La. 1992). Laboratory owes employee a duty to perform test in a scientifically reasonable manner: *Lewis v. Aluminum Co. of Am.*, 588 So.2d 167, 170 (La.Ct.App. 1991); writ denied, 592 So.2d 411 (La. 1992). Laboratory owes employee a duty to perform tests in a competent, non-negligent manner: See *Herbert v. Placid Ref. Co.*, 564 So.2d 371, 374 (La.Ct.App. 1990).
7. *Harvey J. Duncan, a/k/a Jim Duncan, Appellant (Plaintiff) v. Afton, Inc.*, a Tennessee corporation, d/b/a Healthcomp Evaluation Services Corporation, d/b/a National Ameritest, a/k/a Ameritest; and Leigh Ann Shears, an individual, Appellees (Defendants). No. 99-24. Supreme Court of Wyoming. Nov. 30, 1999. (Cite as: 1999 WL 1073434 (Wyo.).)
8. Claims have been made against MROs, and there have been significant settlements.

9. The general legal duty to remove individuals from safety-sensitive positions is found in 49 C.F.R. 40.23. The prohibition against removing an individual prior to MRO verification is found in 49 C.F.R. 40.21.
10. Didrex is a prescription drug that will cause a positive methamphetamine result. Adipex is a prescription drug that is used as an appetite suppressant; it will not cause a methamphetamine result.
11. It is worth noting that although the actual quantitative value for the methamphetamine was never reported, the initial laboratory result to the MRO reported the presence of methamphetamine only. This means that the amphetamine level was under 500 ng/ml, and such a laboratory result is consistent with inhaler use.
12. Such a practice of universal direct observation of micturition (the process of emptying the bladder) or even the suggestion of doing so, would quickly erode a great deal of public support for drug testing. It may also be viewed as unnecessarily invasive, and trigger various challenges to mandatory drug testing as being an unreasonable invasion of privacy. In fact, many state drug-free workplace statutes require privacy in providing urine specimens. DOT regulations are quite specific on this, and a number of courts have suggested that an observed collection of urine in the absence of individualized suspicion could be viewed as the tort of common law invasion of privacy (e.g., *Borse v. Piece Goods*, 963 F.2d 611 (3d Cir. 1992), applying Pennsylvania law). In *Borse*, the plaintiff was discharged for refusing to submit to urinalysis screening and to personal property searches at the workplace. The federal appellate court predicted that, if faced with the issue, the Pennsylvania Supreme Court would find a public policy exception to the employment-at-will doctrine based on the common law tort of invasion of privacy if the employer was going to require Mrs. Borse to provide urine under observed collection (in the absence of individualized suspicion).

17. 1998 DOT regulations, 49 C.F.R. Subtitle A, §40.25(f)(22)(ii).
18. See also 2001 DOT §40.355: “What limitations apply to the activities of service agents? As a service agent, you are subject to the following limitations concerning your activities in the DOT drug and alcohol testing program. (a) You must not require an employee to sign a consent, release, waiver of liability, or indemnification agreement with respect to any part of the drug or alcohol testing process covered by this part (including, but not limited to, collections, laboratory testing, MRO, and SAP services). No one may do so on behalf of a service agent.”
19. GAO-05-653T: “Drug Tests: Products to Defraud Drug Use Screening Tests Are Widely Available.”
20. Department of Health and Human Services, Substance Abuse and Mental Health Services Administration. Proposed Revisions to Mandatory Guidelines for Federal Workplace Drug Testing Programs, April 13, 2004 (69 FR 19673-01).
21. On-site oral fluid testing devices are available but are essentially ineffective at identifying the parent drug THC in specimens. THC is the target for oral fluid testing since the amount of metabolite (THC-COOH) found in urine is found in very small quantities in the mouth.
22. *Alberto R. Gonzales, Attorney General, et al., Petitioners, v. Angel McClary Raich et al.* No. 03-1454. Supreme Court of the United States. Decided June 6, 2005. 125 S.Ct. 2195.
23. In the Supreme Court of the United States, *John D. Ashcroft, Attorney General, et al., Petitioners v. Angel McClary Raich, et al.* On Writ of Certiorari to the United States Court of Appeals for the Ninth Circuit, No. 03-1454. Brief for the Petitioners, Paul D. Clement, Acting Solicitor General.
24. *Washburn v. Columbia Forest Products, Inc.*, 197 Or App 104, 104 P3d 609 (2005).
25. The U.S. Supreme Court had held that a person is not disabled under federal disability law if a mitigating measure will alleviate an otherwise substantial limitation to a major life activity. See, e.g., *Sutton v. United Airlines, Inc.*, 527 US 471, 119 S Ct 2139, 144 L Ed 2d 450 (1999).
26. What appears circular in applying the mitigation rule to the use of medical marijuana is that the decision essentially prohibits the employee from taking advantage of the very medication that alleviates his purported disability.

CHAPTER 11

Point of Collection Drug Testing

Edited by Dennis J. Crouch, M.B.A.

Director, Sports Medicine Research and Testing Laboratory, and Co-Director, Center for Human Toxicology, University of Utah, Salt Lake City, Utah, and Consulting Toxicologist, The Walsh Group, P.A., Bethesda, Maryland

Point of collection testing (POCT) utilizes some of the least-sophisticated drug testing technology, yet has been quite controversial. The earliest on-site facilities used instrumented-immunoassay techniques for testing. Despite acceptance of the technology for laboratory testing, its use at the site of specimen collection was questioned due to scientific, ethical, and medicolegal concerns about confidentiality of the donor and donor results, the lack of confirmation, proficiency of the operators, security of the facilities, quality control, and a host of related issues. However, the demand for immediate drug test results from clinical, workplace, and criminal justice settings fueled the continued growth of POCT and POCT technologies. The introduction of non-instrumented and subjectively interpreted POCT devices has added to the controversy surrounding on-site testing, but has provided an innovative new approach to drug and alcohol detection. The scientific skepticism about the reliability of these devices was often warranted because early products had varying sensitivity, specificity, and accuracy. However, there has been an evolution of the technology, as discussed in Section 11.5, such that the products are more reliable and the technology more widely accepted. A primary motivator for product and technology development and improvement has been the criminal justice system. Here, as discussed in Section 11.2, testing is routinely performed in pretrial, pre-sentencing, probation, parole, incarceration, and drug treatment programs. In the identification of impaired drivers, POCT also evolved from instrumented breath alcohol testing instruments to handheld devices (see Section 11.4). Some of the most recent advances in POCT have involved the analysis of alcohol and other drugs in oral fluids. As discussed in Sections 11.1 and 11.4, instrumented and several non-instrumented devices are now available. Oral fluid collections are less invasive and problematic than urine collections, making POCT using this specimen a fertile area of product development and scientific research.

Federal, state, and local regulations have often changed the face of laboratory science. Based on pending regulations discussed in Section 11.3, oral fluid and urine testing devices, analysts, procedures, and facilities may soon be required to conform to standards similar to those imposed on conventional urinalysis drug testing. This is potentially a very significant development because (1) the previous urine regulations had a sweeping impact on drug testing and its allied industries, and (2) many of the scientific, ethical, and medicolegal concerns about POCT are addressed in the pending regulation.

11.1 POINT OF COLLECTION TESTING OF ALTERNATIVE SPECIMENS (OTHER THAN URINE)

Alain Verstraete, M.D., Ph.D.¹ and J. Michael Walsh, Ph.D.²

¹ Ghent University Hospital, Laboratory of Clinical Biology–Toxicology, Ghent, Belgium

² The Walsh Group, P.A., Bethesda, Maryland

In 1984, Rodgers et al.¹ developed an enzyme-channeling test strip immunoassay for the detection of cannabinoids in saliva. The limit of detection was 10 ng/ml of THCCOOH. The antibody had high cross-reactivity for THC, and the test was positive for 2 to 2.5 h after smoking. Since the mid-1990s, there has been a growing interest in POCT testing of alternative specimens for drugs.

Some authors and device manufacturers have attempted to use POCT tests (designed for urine) to test alternative matrices, but with mixed results. Indeed, in alternative matrices, the drug concentrations are often lower than in urine and the parent molecules are excreted, more than the metabolites. Therefore, antibodies with other target molecules must be used. Iwersen and Schmoldt² tried to adapt the Boehringer Frontline urine assay (which was subsequently used in the Drugwipe) for analysis of saliva. By increasing the contact time of the saliva specimen to the collection pad they could perform the analysis; however, up to 8 min was needed in some cases to obtain sufficient moistening of the pad. They observed no false-positive, but many false-negative cases. The sensitivity of the modified procedure was 73, 53, and 75% for cocaine, cannabis, and opiates, respectively.

The first on-site or point of collection testing (POCT) devices that were commercially available for oral fluid analysis were the Securetec Drugwipe® (that could be used for sweat as well), Avitar Oralscreen™, and Cozart Rapiscan. The European project Rosita³ (Roadside Testing Assessment) was the first large-scale evaluation of POCT oral fluid and sweat testing devices and it provided a strong impetus for further development of POCT products for saliva/oral fluid and sweat.

Most POCT research and development efforts in the last 5 years have been directed toward testing of saliva/oral fluid. Although some testing of perspiration/sweat has been done, this has been done on a much more limited scale. To the authors' knowledge, no point-of-collection tests currently exist for hair or nails.

Table 11.1.1 gives possible applications of oral fluid POCT devices. The main applications are workplace and roadside drug testing. As of the beginning of 2004, POCT oral fluid tests are being used in prisons and some workplaces (mining, printing, transportation, and manufacturing). POCT roadside controls by police using alternative matrices such as oral fluid have generally only been performed on an experimental basis, although legislation introduced in December 2003 in the state of Victoria in Australia will eventually allow police to perform roadside oral fluid tests for cannabis and methamphetamine.⁴

In the U.K., the Cozart Rapiscan has been in use since 2001 by the Home Office to test for drugs of abuse (cocaine and heroin) in arrestees detained in police custody.⁵

11.1.1 Testing Devices/Techniques

11.1.1.1 Examples of Devices

During the Rosita project,³ three POCT devices for saliva and one device for sweat were identified. However, by the end of 2003, ten different devices were commercially available (Table 11.1.2).

11.1.1.2 Principle of Example Testing Methods

Most rapid oral fluid and sweat tests use the lateral flow immunoassay technology, typically with visual evaluation of the results. However, some of the devices can be coupled to electronic readers and the results read automatically.

Another technology, the UPLink™ POCT *in vitro* diagnostic system, uses Up-Converting Phosphor Technology (UPT™). UPT particles are small ceramic nano-spheres composed of rare earth metals. These particles are similar to the particles excited by ultraviolet light that have been used for decades in television display screens and fluorescent tubes. However, unlike the particles used in television screens, UPT particles are excited by infrared light and they “up-convert” the energy to give a visible emission. The use of infrared light (rather than ultraviolet light) to create a colored signal is called up-conversion. Because no other materials in nature up-convert, biological specimens will not emit light when excited by infrared energy. Therefore, tests using these particles are unaffected by specimen background, resulting in a very sensitive assay system especially when linked to well-designed antibodies. In addition, just like current television display screens, UPT particles are available that emit different colors, which allows multiplexing. UPT labels have been incorporated into a rapid lateral flow test format and a portable, bench-top instrument was developed to read the lateral flow test strips using compact laser diodes.⁶

11.1.1.3 Operation (General)

One can divide the available POCT devices along a continuum of complexity of operation, from those very easy to operate devices to those that are more complex to operate. Three examples are discussed below: Branan Medical Oratect™ (Figure 11.1.1), Securetec Drugwipe (Figure 11.1.2), and OraSure Technologies Uplink™ (Figure 11.1.3).

Branan Medical Oratect (two steps, total analysis time about 5 to 10 min)

1. Collect an oral fluid sample by placing device inside the donor mouth on the inner cheek. The collection pad should touch the donor's cheek.

Figure 11.1.1 Branan Medical Oratect. The test shows the control line and a line in the area of the amphetamines, methamphetamine, cannabis, cocaine, and opiates, which means that none of the tested drugs was found in the sample.

Figure 11.1.2 Securetec Drugwipe II. The test shows two control lines and a line in the area of the amphetamines/methamphetamine/ecstasy, cannabis, cocaine, and opiates, which means that all of the tested drugs were found in the sample.

2. After 10 s, move the device to the bottom of the mouth under the tongue. Leave the device under the tongue until the colored lines appear in the viewing windows indicating that a sufficient volume of saliva has been collected, and then remove the device from the mouth.
3. Read the results visually within 9 to 11 min after removing the device. Do not read results after 11 min because the intensity of the colored line may change.

Securetec Drugwipe (three steps, total time is about 5 to 10 min)

1. Disconnect wiping section from the device.
2. Wipe the surface of the tongue or the body (if testing for drugs deposited on the skin) for approximately 10 s.
3. Reassemble the device, dip the absorbent pad into water, and remove after counting to 10.
4. Read the result visually after approximately 10 min.

OraSure Technologies Uplink/Dräger Safety Drugtest (eight steps, total analysis time is about 16 min)

1. Insert sample preparation cartridge (SPC) into the cassette.
2. Align lower tabs with notches on cassette and press until it “clicks.”
3. Remove cap of SPC and store.

Figure 11.1.3 The Dräger DrugRead with the optional keyboard and printer and the sample collection device.

4. Collect an oral fluid sample with the collection sponge.
5. Express fluid from the sponge by pressing the collection device into SPC until it “cracks.”
6. Remove collection device wand by twisting it counter-clockwise.
7. Replace cap on SPC until it is fully seated.
8. Incubate the sample for 4 min.
9. Twist SPC clockwise to align upper tabs with notches on cassette and press down until SPC wings contact test cassette rim.
10. Run test on the reader (this takes 8 min).

The total procedure takes 16 min.

11.1.1.4 Evaluations of Devices

The following is a compilation of information about field testing of the ten oral fluid/sweat POCT devices that we identified. Much of the information presented below comes from studies conducted by, or sponsored by, the device manufacturers. Some of the devices discussed are not yet commercially available (e.g., OraSure Uplink, Lifepoint Impact, and Envitec-Wismar Smartclip).

Three devices were evaluated during the first Rosita study.³ The results (Table 11.1.3) show that their reliability was not sufficient, but differences in confirmation techniques and prevalence of positive samples made comparisons difficult. However, most of these devices have been significantly modified since the Rosita study to improve their sensitivity and reliability. Some of the POCT devices identified have already been extensively evaluated, while others have not. Recently, Walsh et al.⁷ evaluated the performance of six devices with drug-fortified oral fluid samples. A summary of the detection limits for the different drugs is given in Table 11.14. For amphetamine, methamphetamine, and opiates testing, several devices could detect concentrations lower than the oral fluid cutoffs mentioned in draft 4 of the SAMHSA guidelines for workplace drug testing.⁸ However, there were some problems in testing cocaine (most devices target benzoylecgonine) and no device could detect THC at the 4 ng/ml recommended cutoff.

The results of field evaluations of the individual POCT devices are given below.

Table 11.1.3 Summary of the Results Obtained with POCT Oral Fluid and Sweat Tests during the First Rosita Study³

Oral Fluid	RapiScan					Drugwipe					Oralscreen				
	n	Prev.	Sens.	Spec.	Acc.	n	Prev.	Sens.	Spec.	Acc.	n	Prev.	Sens.	Spec.	Acc.
Amphetamines	80	73%	83%	68%	79%	120	74%	87%	55%	78%					
Benzodiazepines	133	47%	17%	90%	56%										
Cannabinoids	9														
Cocaine	33	0%	—	100%	100%	118	25%	59%	92%	84%	190	2%	25%	84%	83%
Opiates	37	49%	61%	26%	43%	46	48%	41%	79%	61%	180	0%	—	99%	99%
Sweat											183	4%	57%	93%	91%
Amphetamines						63	92%	94%	67%	92%					
Cocaine						22	100%	77%	—	77%					
Opiates						9	100%	89%	—	89%					

Note: All POCT results were compared to GC-MS in oral fluid/sweat, except for benzodiazepines, where they were compared to blood.
Abbreviations: n: number of comparisons, Prev: prevalence of positive samples, Sens: sensitivity of the test, Spec: specificity of the test, Acc: accuracy of the test, = number of true positives and true negatives divided by the number of tests.

Table 11.1.4 Detection Limits (ng/ml) of Six POCT Tests in Spiked Oral Fluid Samples^{7,32}

	Amphetamine	THC	Morphine	Cocaine	Methamphetamine
Drugwipe	500	50	20	200	100
Oratect	25	ND	20	40	25
Rapiscan	25	50	80	200	100
OraLab	500	100	80	10	500
Saliva screen	NT	ND	20	40	25
Uplink	25	20	20	200	25

NT: not tested; ND: no THC could be detected, even at 100 ng/ml.

Orasure Technologies Uplink/Dräger Safety Drugtest

After drinking 200 ml of Coca tea, benzoylecgonine could be detected during for 22.5 to 27.5 h. Using a GC-MS/MS limit of detection (LOD) of 0.4 ng/ml benzoylecgonine, the Dräger DrugTest demonstrated a sensitivity, specificity, and accuracy of 86, 87, and 86%, respectively.⁹

The Dräger DrugTest was also evaluated using samples from 92 patients in an addiction treatment program. The Dräger DrugTest results were compared to GC-MS/MS and the sensitivity, specificity, and accuracy were 95.2, 90.1, and 91.3% for THC; 87.5, 96.4, and 95.7% for cocaine; and 92.9, 84.4, and 87.0% for opiates.¹⁰

The Dräger DrugTest was further evaluated by the German police during drug controls during the Love Parade of 2003. The accuracy of the POCT device, compared to GC-MS or GC-MS/MS, was 91.5% for THC, 97.2% for cocaine, 100% for opiates, 95.8% for methamphetamine, and 74.6% for amphetamine (S. Steinmeyer, presented at the 41st TIAFT meeting, Melbourne, Australia, November 2003).

In a study using volunteers who smoked marijuana cigarettes, the Uplink rapid drug test was able to detect THC up to 24 h after smoking. The concentrations of THC collected by the Uplink collector ranged from 3.6 to 13,860 ng/ml over the 24-h period of the study. ROC (receiver operating characteristic¹¹) analysis of the data showed a sensitivity of 90% and a specificity of 97.2% using an Uplink screening cutoff of 25 ng/ml with a 15 ng/ml confirmation cutoff. The concentrations in samples collected with the Uplink collector were high when compared to other commercially available devices. Also in passive smokers, a THC concentration of 25 ng/ml was observed. (S. Niedbala, presented at the 41st TIAFT meeting, Melbourne, Australia, November 2003).

Dräger Safety decided in August 2005 to discontinue the marketing of the Uplink/DrugTest system, but the company is developing a new 2nd Dräger DrugTest Generation for mobile drug screening applications.

Securetec Drugwipe

One of the first evaluations of the Securetec Drugwipe I was performed by Kintz et al.,¹² who administered 60 mg of codeine to six volunteers and analyzed their oral fluid (by wiping on the tongue) and sweat (by wiping the forehead) with the Drugwipe. The foreheads of the subjects were swabbed for 10 s at 1, 4, 9, and 24 h after codeine administration. In all subjects (except one) the Drugwipe tested positive for opiates. However, some false-negative results were observed. In the second part of the study, the tongues of the subjects were carefully wiped at specific times over a period of 24 h, and at the same times a specimen of saliva was collected. Although codeine could be detected using the Drugwipe, numerous false-negative results were observed compared to GC/MS. The authors attributed the false-negative results to the codeine concentrations being too low to be detected by Drugwipe, the presence of interfering substances in saliva, or to inadequate sampling procedures.

For sweat testing, the first-generation Drugwipe was introduced to routine work by the police in Baden-Württemberg (Germany) after a successful study. A preliminary evaluation of the amphetamine tests showed good sensitivity and reliability, especially for ecstasy.¹³

However, the police determined that the cannabis test showed poor reliability. After intake of 100 mg of MDMA by two volunteers, the Drugwipe could detect MDMA in sweat taken from the armpit in a time window of 2 and 12 h.¹⁴

With the use of the Drugread optical reader to read the Drugwipe results, MDMA could be determined in oral fluid quantitatively and could be detected for up to 24 h.¹⁵

Lifepoint Impact Test System

In an experimental setting, the limit of detection for THC was 5.5 ng/ml (Wang et al., poster at the SOFT meeting in Milwaukee, October 2000). No results of field evaluations have been published or presented at the time of writing. *Note:* Effective April 28, 2005, LifePoint assigned its assets in trust to the Insolvency Services Group, Inc.

Varian On-Site OraLab

No field evaluations have been presented or published.

Sun Biomedical Laboratories OraLine s.a.t. Test

No field evaluations have been presented or published.

Avitar ORALscreen

Barrett et al.¹⁶ compared the ORALscreen to urine results in drug users in inpatient substance abuse clinics and in a probation department. The agreements with known positive results were 96, 96, 86, and 43% for cocaine, opiates, methamphetamine, and THC, respectively. For negative results, the agreements were 92, 96, 94, and 76%, respectively. After consumption of poppy-seed bread, the opiate results were positive for 1 h.

Branan Medical Corporation Oratect

With samples fortified at concentrations 300, 100, 75, 50, and 25% of the cutoff, the sensitivity was 80% for all assays, except morphine (90%), and the specificity was 97.1% for THC, PCP, amphetamine, and methamphetamine, and 98.6% for cocaine and morphine.¹⁷ An evaluation of 40 oral fluid samples from donors with negative urine drug tests all showed negative Oratect results. In donors with positive urine drug tests, Oratect gave positive results in 12/13 cases for cocaine, 13/13 for morphine, 1/2 for methamphetamine, and 7/8 for THC.^{18,19}

After administration of 10 mg of codeine to ten volunteers, all subjects tested positive up to 4 h with the Oratect (with a cutoff at 20 ng/ml). At 6 h, six out of ten volunteers tested positive. The Oratect results correlated well with the Intercept device showing low to undetectable opiate concentrations at 6 h.

An evaluation of the Oratect benzodiazepines assay using fortified samples and samples that were positive by GC-MS confirmed the cutoff of 15 ng/ml oxazepam. All samples that were positive by GC-MS were positive by Oratect. The detection limits varied between 5 ng/ml for temazepam, over 30 ng/ml for nordiazepam to 150 ng/ml for chlordiazepoxide (R. Wong, poster at the 41st TIAFT meeting in Melbourne, Australia, November 2003).

Cozart Bioscience Rapiscan

Jehanli et al.²⁰ evaluated the Cozart Rapiscan after administration of marijuana and 16 mg of codeine to human volunteers. Codeine could be detected for 9 h in all subjects and at 24 h in three

out of five subjects, but marijuana could not be detected for more than 1 or 2 h (at the time of the evaluation, the detection limit was 150 ng/ml of THC in neat saliva) in the subjects.

Moore et al.²¹ compared the Rapiscan methadone and opiates tests on 50 samples collected from patients attending a substance abuse clinic to EIA and GC-MS. Compared to GC-MS, the methadone test had 100% sensitivity and specificity, the opiate test had 100% sensitivity and 92% specificity.

De Giovanni et al.²² evaluated the Rapiscan (except the cannabis test) on using drug-fortified saliva samples, samples from methadone treatment patients and young people at the exit of a discotheque. No false-positive results were obtained. In the drug-abusers group, no opiates and benzodiazepines were present and only one of three cocaine-positive cases was detected. For methadone, 15 of the 21 positives were detected. The three amphetamine cases were detected with the Rapiscan. In the discotheque goers, no opiates, methadone, or benzodiazepines were observed. All positive amphetamines and two of three cocaine cases were detected. All volunteers accepted the sampling without problems.

The Rapiscan cocaine and opiate assays were evaluated by the Forensic Science Service (an executive agency of the U.K. Home Office that supplies forensic services to police forces in England and Wales). Drugs could readily be detected for 24 to 36 h after last admitted use. For the cocaine assay, compared to EIA ($n = 1081$), 10.4% true positives, 86.5% true negatives, 0.6% false positives, and 2.5% false negatives were observed. With GC-MS, 80.6% of the positive samples were confirmed. For the opiates, compared to EIA ($n = 1060$), 50.5% true positives, 29.2% true negatives, 0.3% false positives, and 20.0% false negatives were observed. With GC-MS, 72.6% of the positive samples were confirmed. Reducing the Rapiscan cutoff by 5% would have decreased the number of false-negative results by more than half. Clinic staff and donors greatly preferred providing oral fluid specimens for drug testing compared to urine. The greatest criticism of oral fluid testing was the time taken to collect samples. In non-drug-using individuals, samples could normally be taken within 2 to 4 min. In regular drug users, sample collection times ranged between 5 and 15 min. In a small number of cases, collection was abandoned when insufficient sample had been collected after 15 min (D. Osselton, personal communication SOFT Annual meeting, October 2001).

Kolbrich et al.²³ evaluated the Rapiscan after controlled administration of cocaine. Compared to an 8 ng/ml cutoff by GC-MS, the Rapiscan had a sensitivity, specificity, and efficiency of 82.7, 94.5, and 87.6%, respectively.

A new collection device that allows for direct analysis (by the Cozart Rapiscan Instrument) of drugs in the oral fluid without the need to use dilution buffer, was evaluated in ten healthy volunteers (five males and five females). The new collector is designed so that collection of about 1.5 to 2.0 ml of oral fluid activates an electric circuit with a LED (light emitting diode). The volume collected from the volunteers varied between 1.3 and 2.0 ml. Completion of collection took a maximum of 5 min with the shortest time 45 s. No chemical stimulant is needed as the device itself is designed to stimulate salivation (A. Jehanli, presented at the 41st TIAFT meeting, Melbourne, Australia, November 2003).

ulti med Products Salivascreen

No field evaluations have been presented or published.

Envitec-Wismar SmartClip

The SmartClip was evaluated by German police forces (Thüringen) mainly in road-side testing from February to June 2003 (S. Fellner, personal communication). The handling procedure of the SmartClip was confirmed to be simple and hygienic. In several cases, additional buffer had to be added onto the collection sponge following oral fluid collection to ensure sufficient sample volume. The reading and interpretation of test results were found to be simple and unambiguous. A

preliminary analysis of the data (54 cases) showed that 13% (6 cases for amphetamine/methamphetamine and 1 case for morphine) of the reported test results were true positive and only 2% (1 case for amphetamine) of the reported test results were false positive. (S. Fellner, presented at the 41st TIAFT meeting, Melbourne, Australia, November 2003).

Noncommercial Assays

Cope et al.²⁴ described a disposable, 10-min, near-patient POCT saliva test to monitor cigarette smoking. A plastic device contains the dried reagents that measure nicotine and its metabolites by a colorimetric assay. The device can be used semiquantitatively by observing a color change and comparing it to a reference chart or quantified by measuring the light absorbance with a colorimeter. This method correlated with cotinine, as measured independently by radioimmunoassay ($r = 0.57$, $P < 0.005$).

11.1.2 Specimens (Saliva/Sweat/Others)

In all oral fluid POCT devices, the sample is collected with a collector that is provided by the manufacturer of the device. Experience has shown that it is important to use the collector that is recommended by the manufacturer. Indeed, obtaining a good sample of oral fluid is one of the most critical parts of testing.²⁵ People who have recently used drugs often have difficulty producing saliva, and it may be very viscous. Some sampling techniques that work well with normal volunteers do not work with drug users, and in this case, some stimulation and/or dilution with a buffer might be needed. However, stimulation of the saliva and use of buffers may affect drug detection and concentration.²⁵ THC is not excreted in saliva and the THC present in the mouth is the result of oral contamination. Sampling devices that wipe the mucosa have a greater yield of THC.²⁶ Moreover, THC also binds to the cotton of the sampling device, and extraction with a solvent might be needed to improve recovery.

Many devices have a reservoir, so the remainder of the sample (that is not used for the POCT testing) can be sent to a laboratory for confirmation by reference techniques.

For sweat, the Drugwipe is the only POCT device that has been used. Sampling is done by wiping the pad over the skin of the forehead or the palm of the hand. No evaluations of the reproducibility of the sampling process have been reported.

Quality Control, Quality Assurance, Proficiency Testing: Most POC immunoassay tests have a built-in control line, and the result is “invalid” if the control line does not appear. In most instances, an invalid result is because the sample volume is not sufficient or the sample is too viscous. There have been some pilot oral fluid POC proficiency testing programs in the U.K. and the U.S. At this time, no established programs exist for oral fluid and *a fortiori* for POCT tests.

Training: Use and interpretation of POCT oral fluid or sweat POC drug tests requires adequate training. Some manufacturers will train and certify the operators of their devices.

Evidentiary Value: POC tests are immunoassays, with their known limitations, e.g., false-positive results due to structurally analogous medications, like phentermine giving a false positive amphetamine result.²⁰ They can only give a presumptive result that has to be confirmed by a chromatographic technique coupled to mass spectrometry.

Advantages, Disadvantages, and Limitations: POC drug tests in alternative matrices have a place in some situations where immediate measures need to be taken, e.g., in enforcing DUID legislation.²⁷ There has been progress in the reliability and the detection limits of the devices, but further improvement is needed. George and Braithwaite²⁸ have reviewed the advantages and disadvantages of using POCT testing for drugs of abuse. They made five recommendations:

1. All devices should be initially evaluated by professional laboratory staff.
2. A cost–benefit analysis should be performed, taking into account consumables and staff time.

3. Adequate training should be given and the operators should understand that they are responsible for any errors in interpretation of the results.
4. Quality control and quality assurance must be covered in addition to proper storage, maintenance, and calibration of the device.
5. Any device should undergo a rigorous evaluation to determine its suitability before it can be marketed.

11.1.3 Developing Technologies

In addition to lateral flow immunoassays and up-converting phosphor technology, some other technologies have been proposed for POCT drug testing in oral fluid.

Surface-enhanced Raman spectroscopy has been applied to analysis of amphetamines in oral fluid.²⁹ Kidwell and Van Wie³⁰ developed a reusable, fieldable, and portable sensor for the detection of cocaine in oral fluid, based on ion selective electrodes for drugs. The data are transmitted by an infrared link to a palm computer. The detection limit was 50 ng/ml in buffered media.

Ion mobility spectroscopy has been tried for the detection of drugs in oral fluid, but to date this has not been successful (N. Samyn, personal communication). However, Skopp and Pötsch³¹ report a preliminary study in which heroin and cocaine use could be detected in skin wipes (with a Salivette moistened with 70% ethanol) of the sternal or axillary region in cases where 6-acetylmorphine, morphine, or cocaine had been found by GC-MS. The skin swabs were directly blotted onto the filter pads and dried with a hairdryer.

11.1.4 Conclusions

There is a strong need for POC testing of alternative matrices, particularly for roadside testing. The use of, e.g., oral fluid has the advantage that the parent drug will be detected and that the presence of a drug in oral fluid may correlate better with impairment than the presence of drug metabolites in urine. Obtaining an oral fluid sample can be done under supervision and without embarrassment. But individuals who have recently consumed drugs often have very little and viscous oral fluid. Therefore, obtaining a suitable sample can take 15 to 20 min or be impossible. There has been tremendous progress in the performance of POC drug tests for alternative matrices; however, more research is needed on the influence of collection, adulterants, and other parameters that could violate the integrity of the specimen, the concentrations seen after passive exposure, and most importantly further research is needed to improve the sensitivity for detection of THC and benzodiazepines.

11.2 POINT OF COLLECTION TESTING IN CRIMINAL JUSTICE

Leo Kadehjian, Ph.D.

Biomedical Consulting, Palo Alto, California

11.2.1 Introduction

With the well-established association between drug use and crime, the criminal justice system is presented with a population with a high prevalence of drug users. Current (2000) data from the Arrestee Drug Abuse Monitoring program (ADAM) surveying arrestees in 35 cities across the U.S. indicate that more than half of all individuals brought into criminal justice systems have substance abuse problems. Of adult male arrestees, 64% tested positive by urinalysis for at least one drug (ranging from 52 to 80% between cities). For female arrestees, 63% tested positive for at least one drug (ranging from 31 to 80%). For juvenile arrestees, 56% of males and 40% of females tested positive for at least one drug.¹

It is critical that the criminal justice system monitor those under its supervision to ensure that ongoing drug use is both detected and deterred. This is most effectively done through urine drug testing which has been demonstrated to be an objective and effective tool.²⁻⁴⁹ Such drug testing is often specifically mandated by law.

Accordingly, there has been a great demand for effective urine drug testing programs within criminal justice contexts. These urine drug testing programs have been implemented in a variety of criminal justice contexts including testing of arrestees before their initial appearance in court, testing imposed by the court as a condition of release pending trial,¹⁶⁻³⁹ pre-sentence testing, testing while on probation or parole,⁴⁰⁻⁴³ and testing within jails and prisons.⁴⁴⁻⁴⁹ Furthermore, drug testing is a cornerstone of effective specialized drug courts,³ community corrections programs, and court-mandated treatment programs.

11.2.2 Point of Collection Drug Testing

By far, the drug testing technology most used in point of collection (POC) testing programs within the criminal justice setting is urine testing. This specimen has the benefit of large specimen volume allowing for multiple tests and retests, including the possibility to split the original specimen at the time of collection ensuring that a second untouched specimen is available in the event of challenges. Furthermore, there are well-established testing methodologies for both laboratory and POC use, and recognized testing procedures and laboratory standards. There is a large body of clinical and scientific literature addressing the detection of drugs in urine. In addition, urine benefits from having drug and/or metabolite concentrations generally 100 times those found in many other body specimens (e.g., blood, oral fluid, sweat, hair). However, urine does suffer from awkward specimen collection procedures and the possibility of specimen adulteration, substitution, and dilution. Nonetheless, urine remains the specimen of choice for drug testing within criminal justice contexts.

Criminal justice drug testing programs have historically utilized commercial laboratories, with trained and experienced scientists, providing assurance of quality results, but with often frustrating delays between specimen collection, transport to the laboratory, testing, reporting of the result, and ultimately responding to the substance user. With the availability of simple, robust, and accurate automated bench-top immunoassay analyzers, many testing programs established their own POC drug testing facilities. Since the first court-based testing laboratory was established in 1971 in the Superior Court of the District of Columbia a wide variety of POC testing programs have been

Table 11.2.1 Comparison between Instrumented and Non-Instrumented Drug Test Devices

Automated Bench-Top Analyzer	Non-Instrumented Devices
Objective read	Subjective read
Suitable for high volume	Suitable for low volume
Rapid turnaround time	Immediate turnaround time
Lower cost/test (\$1/drug)	Higher cost/test (\$1–3/drug)
Daily calibration/controls	No calibration/use internal control(s)
Established QC practices	Undefined QC requirements
Established proficiency testing programs	Proficiency testing programs available
Hardcopy print-out	No hardcopy print-out
Established case law	Little case law
Repeat testing often meets due process	Due process requirements uncertain

implemented nationwide. These programs have recognized the value of rapid drug test results with the benefit of immediate responses to ongoing drug use, as well as immediate positive reinforcement for not using drugs. For many of these criminal justice applications, POC bench-top automated immunoassay analyzers have been used successfully for many years. For example, within the U.S. federal courts, at least 20 pre-trial and probation drug testing programs use automated immunoassay analyzers, with a few even using sophisticated high-volume analyzers as found in clinical and commercial laboratories. Many of these POC testing programs using simple bench-top automated immunoassay analyzers have their testing competently performed by officers who have been trained and certified by the test system manufacturer, although they may have had no other formal laboratory training. In addition, these POC testing programs within the federal courts are subjected to rigorous on-site inspections, and participate in quarterly blind proficiency testing, demonstrating excellent performance. Test results from these POC testing programs have been repeatedly upheld in numerous legal challenges. A 1991 National Institute of Justice study of drug testing technologies recognized that on-site automated immunoassay analyzers demonstrated performance equal to commercial laboratory-based testing.¹⁰

Although POC bench-top automated analyzers offer the benefits of rapid turnaround time, objective hard copy results, reduced test costs (dependent on volume), and a proven track record of performance and admissibility in a variety of legal and administrative proceedings, not all criminal justice testing programs have either the budget or a sufficient number of specimens to justify having an automated analyzer at the point of collection. Furthermore, there may not be the availability of a dedicated and properly trained staff member to operate the analyzer.

However, as a result of impressive advancements in immunoassay technology, urine drug tests as performed on automated analyzers have now been made available in simple, rapid, easy to use, visually read test strips. Such non-instrumented test strips allow for rapid, accurate, and reliable testing in those sites that cannot justify an automated analyzer as well as in numerous field situations.

Some of the key comparative issues between on-site automated analyzers and non-instrumented drug testing devices within a criminal justice setting are shown in Table 11.2.1.

11.2.3 Non-Instrumented POC Drug Tests

There are a wide variety of non-instrumented drug test devices available, from simple dipsticks, which are briefly inserted into a specimen and then allowed to develop over a few minutes, to cassettes where a few drops of the specimen are added with a plastic pipette or calibrated syringe, and even specimen collections cups with the test strips incorporated directly into their walls or cap, which obviate any handling or pipetting of the specimen. Furthermore, many of the non-instrumented test devices are available in single drug assay or multidrug assay formats. For all of these devices, the test results are available in anywhere from 3 to 15 min. These devices utilize well-established immunoassay technologies (described in detail in other chapters of this section), with

antigen–antibody reactions similar to the automated instrument homogeneous immunoassay technologies. However, for these test strips the antigen–antibody reaction occurs on chromatographic test strips and so they are considered solid-phase immunoassays. The immunoassay strips are labeled with antibodies directed to the specific drug and/or drug metabolites to be detected. The test results are read visually within a few minutes as the presence or absence of a colored line at a specified position on the strip pertaining to each drug in question. The test strips also have control lines so each test is in part internally controlled. The great interest in these devices is evidenced by the rapid proliferation of the wide variety of these devices, and numerous manufacturers and even more distributors.

However, there has been ongoing concern that these simple, visually read devices may not provide sufficient scientific or forensic accuracy for use in some of the above-mentioned criminal justice applications. The concerns of the accuracy of these devices are based mainly on the subjective nature of visually reading the test results as the presence or absence of a colored line. There has been a concern that specimens with drug concentrations at or near the specified test cutoff concentration may yield indeterminate lines challenging the reader to determine if the result should be called positive or negative. The device package inserts indicate that any such equivocal or borderline results should be reported as negative, taking a conservative approach. There even are a few POC testing devices that utilize a small electronic reader to provide an objective readout of the result. Such readers are available not only for POC urine test devices but also for POC oral fluid testing.

Since the introduction of POC non-instrumented urine drug testing strips in the 1980s, there have been numerous technological advancements and performance improvements such that many of these devices perform quite well. There have been numerous positive performance evaluations of these devices presented at scientific meetings and in peer-reviewed scientific publications (see References 50 to 53 and references cited therein). In 1996, the Administrative Office of the U.S. Courts commissioned a comprehensive study of the available non-instrumented urine drug testing devices. That study of 15 non-instrumented devices found that many of these devices performed amazingly well, especially considering a challenging specimen set, artificially weighted around the immunoassay cutoffs, with accuracies (against the gold standard of GC/MS confirmation) comparable to a commonly used automated bench-top analyzer. The non-instrumented devices demonstrated an overall accuracy of 71% (52 to 79%) vs. the automated analyzer's average of 80% (78 to 82%).⁵¹

A second similar comprehensive study was commissioned in 1998 by the Substance Abuse and Mental Health Services Administration (SAMHSA) with similar impressive results, with the 15 devices demonstrating an overall accuracy of 70% (61 to 78%) vs. automated analyzer 76%.⁵¹

It is important to remember that these studies used artificially weighted specimen sets with drug concentrations around the cutoffs to challenge the devices. With specimens that were drug-free or had much higher concentrations of drugs the accuracies of the devices were much higher. These devices are expected to demonstrate even higher accuracies with specimen populations actually encountered in routine criminal justice settings.

There are also concerns about accuracy since in a criminal justice setting the tests may likely be performed by nontechnical staff without formal laboratory experience. To address use of these devices by nonscientists, a more recent study, also utilizing challenging near cutoff specimens, had results independently read by both a scientist and a nonscientist with almost identical performance.⁵⁰

It should be noted that some devices prove to be relatively “aggressive”; that is, they give positive results for specimens with amounts of drug just below the specified cutoff. It is important to note that these positive results should not be considered false positives when they have in fact correctly identified drug use. The device in fact may be correct in accurately identifying drug presence but simply at a concentration that may not always confirm when subjected to laboratory based testing, e.g., using SAMHSA GC/MS confirmation criteria. It should also be noted that some devices proved to be relatively “conservative,” missing some specimens with drug concentrations at or slightly above the specified cutoff.⁵⁰

Furthermore, the performance of these and other unit test devices have undergone regulatory review by numerous agencies: by the U.S. Food and Drug Administration (FDA) establishing regulatory criteria for clearance for marketing; by the SAMHSA for potential application in federally-regulated workplace drug testing programs;⁵⁴ by a wide variety of criminal justice agencies; and by laboratory accreditation and standards organizations such as the College of American Pathologists (CAP), the Center for Medicaid and State Operations (CLIA regulations), and the National Committee for Clinical Laboratory Standards (NCCLS).

In spite of the impressive performance of such simple, rapid, and easy-to-use devices, there appears to be a consensus within the laboratory community that the results of these devices alone should not be used to impose significant sanctions without some form of further confirmation testing. It is interesting to note that, although these devices are now being widely used in numerous settings, there is little significant case law where there has been detailed judicial scrutiny of the accuracy of these devices and whether use of these devices fulfills the due process requirements in each of the variety of criminal justice settings.

11.2.4 Detection of Adulteration/Dilution

One limitation to the use of urine as a specimen for drug testing is the potential for specimen adulteration, substitution, and dilution. Given that urine specimen collections in the criminal justice context are generally performed under direct observation, the possibility of adulteration or substitution is minimized. In fact, by performing the drug test immediately upon specimen collection, the opportunity for an adulterant to be effective may be minimized because often some time is required for the adulterant to perform its disruptive chemistry. However, specimen dilution through excess fluid ingestion is an issue that merits careful attention. To address these challenges to effective testing there are a variety of POC devices to assess specimen integrity. These include handheld refractometers to measure specific gravity, as well as simple dipsticks, which can assess a variety of adulterants, oxidants, pH, and creatinine. Some of the non-instrumented drug test devices actually incorporate such specimen validity tests in the test device. Non-instrumented devices may also offer indications of inappropriate specimens or failure of the test to perform properly through the use of built-in control lines.

11.2.5 Other Issues

There are some additional issues to consider when an officer is asked to perform drug testing in the presence of a defendant or offender. Officers may be resistant to taking on testing responsibilities as they may feel it is not part of their job function. The officers may also fear increased risk of exposure to infectious disease in handling urine specimens (although the 1991 OSHA Bloodborne Pathogen Regulations, 56 FR 64004, recognized the extremely low risk from casual exposure to urine specimens when not visibly contaminated with blood). There is also the potential for physical harm when confronting a potentially violent offender with a positive drug test result. It may be easier for the officer to deal with a confirmed positive report from a formal laboratory than with a presumptive positive test result from a non-instrumented device. Despite these concerns, there are clear benefits in the use of these non-instrumented drug test devices in front of the offender. Many offenders, when told of the accuracy of the device, will admit to drug use even as the test is being run. Furthermore, when faced with a positive test result many will admit to drug use. In contrast, it is rare for an offender to admit to drug use when the specimen is collected for shipment to an off-site laboratory. Also, when on-site test results are negative, the officer can provide immediate positive reinforcement for maintaining abstinence. When on-site test results are positive, the officer can confront the issue directly and immediately, rather than later dealing with “prior” drug use.

11.2.6 Other Technologies

There are several other specimens and technologies used within the criminal justice system to detect drug use. These include oral fluid testing, sweat patch testing, hair testing, oculomotor testing, and trace drug residue analysis. Hair testing and sweat patch testing are not considered POC testing technologies as the specimens must currently be sent to a laboratory for analysis.

Oral fluid testing is certainly getting attention as a specimen suitable for a variety of POC testing contexts, especially roadside testing.^{55,56} There are both laboratory based methods as well as a few POC testing devices, similar to the POC urine testing cassettes. The main benefit of oral fluid is the ease and gender neutrality of specimen collection. That oral fluid as a specimen for drug testing has reached a level of scientific acceptance is manifested by the fact that SAMHSA has included oral fluid through four rounds of draft guidelines for updating federally regulated workplace testing programs.⁵⁴ Note also that saliva has been well recognized as a suitable specimen for alcohol testing and is allowed under the Department of Transportation's non-evidential on-site alcohol testing procedures.

Another recent technology being promoted to the criminal justice community is oculomotor testing.⁵⁷⁻⁵⁹ With these devices, the eyes' response to a flash of light is objectively measured, and by comparison to the person's own baseline or population averages, a determination of exposure to drugs is made. It has been demonstrated that drug use can have detectable effects on various involuntary oculomotor function parameters. Numerous clinical studies examining the effects of drugs incorporate some of these ocular assessments. However, the ability of such oculomotor assessments to reliably and effectively detect drug *use* as opposed to *impairment* has not been convincingly demonstrated in the peer-reviewed scientific literature. Although these devices appear to have gained interest from the corrections community, there is little published literature from controlled-dose studies, neither are there epidemiological data from field studies, from which an accurate assessment of the performance of these devices can be made or a determination of their relative performance compared to other testing technologies such as urine or oral fluid testing. However, their ease of use certainly merits further research into their performance capabilities.

Another technology occasionally found within corrections settings is a device designed to detect trace amounts of drugs on persons, not only inmates, but also those visiting prisons and even prison staff.⁶⁰

11.2.7 Regulatory Issues

There are few formal regulations specifically regarding drug testing technologies in criminal justice contexts. Although there are several statutory requirements regarding drug testing within corrections settings, these statutes are generally broadly worded leaving specifics about technologies up to those implementing the testing requirements. Generally, the major issues involve whether there must be confirmation testing (generally specified as GC/MS) before certain sanctions may occur.

The Federal Bureau of Prisons has a statutory requirement that, for those serving their sentence in a contract community treatment center, all positive test results be validated to substantiate the positive result (28 CFR §550.42(c)). The current federal probation regulations also require that if a probationer is to be returned to prison based on a drug test, it must be confirmed by GC/MS at a SAMHSA-certified laboratory. Otherwise corrections-based urine drug testing programs are generally not otherwise strictly regulated. However, in order to withstand legal scrutiny, such on-site testing programs should conform to standards of good laboratory practice, including quality control practices and participation in proficiency testing. The on-site testing programs of the U.S. federal courts utilizing automated analyzers have been following such practices for many years, including on-site inspections and participation in external proficiency testing. Quality control practices, external proficiency testing, and appropriate inspection criteria are now being developed for such programs within the federal courts utilizing non-instrumented drug testing devices.

Any criminal justice drug testing program should take into account any state or federal regulations regarding drug testing in other contexts, such as workplace testing, as these standards may be brought up in any challenge to the criminal justice testing program. However, due process issues are generally diminished within a criminal justice context, and accordingly drug testing programs and technologies may be held to a lower standard than in workplace testing. Another concern should be state and federal regulations addressing laboratories in general. These regulations typically apply to clinical laboratories, and corrections-based testing programs are generally not considered to be “clinical.”

11.2.8 Legal Issues

There has been a long history of drug testing within corrections settings and, accordingly, ample case law regarding many aspects of such corrections-based testing programs. There is ample case law precedent in many criminal justice contexts for the admissibility of instrumented immunoassay urine drug testing, both when performed in a laboratory and when performed at the point of collection. Most of these cases uphold the use of repeat immunoassay testing as meeting the due process requirements for use in prison disciplinary hearings and even in probation revocations, without additional confirmation testing.

Currently, there have been few significant cases specifically addressing non-instrumented drug testing technologies, at least at the appellate court level. This may be in part because these tests are rarely being used alone for imposing sanctions without some form of confirmation testing. One area where legal challenges could occur would be the admissibility of the test results themselves, arguing that the testing technology is new and of either unproven or insufficient scientific validity. The aforementioned performance studies should be persuasive in demonstrating the scientific reliability and acceptance of these devices. A question that requires resolution is whether these non-instrumented devices are accurate enough to be used alone or with repeat testing, but without further confirmation testing by an alternative technique, such as GC/MS.

In order for non-instrumented drug test results be used in these various corrections contexts, not only must the inherent performance of the devices be demonstrated, but also whether the devices are properly used. Issues such as operator training, proper chain of custody, specimen handling, device and ancillary storage conditions, and record-keeping procedures must be documented. On-site inspection of these non-instrumented testing programs as well as participation in external proficiency testing programs will also be important components in assessing the admissibility and weight such non-instrumented drug testing evidence should receive. Within the federal courts’ pre-trial and probation on-site testing programs, appropriate inspection checklists and proficiency testing programs are being developed and implemented for use of these non-instrumented drug test devices.

It must be recognized that the due process requirements vary depending on the corrections context, from a fairly low “some evidence” standard in prison disciplinary hearings, to a “beyond a reasonable doubt” standard in criminal cases, with these non-instrumented drug test devices demonstrating overall accuracies on the order of 70%, even in studies that generally meet even the preponderance of the evidence standard (>50%) and possibly even the higher “clear and convincing” evidence standard. Certainly this would be the case for assays for cannabis or cocaine, where cross-reacting substances are minimal and accordingly interpretation of test results is relatively straightforward. However, it is unlikely that these devices alone would be held to meet the beyond a reasonable doubt standard (95% or higher). It is important to note that these devices would be expected to demonstrate accuracies well beyond the 70% observed with near-cutoff specimens, when testing specimens within the criminal justice context with a less-challenging concentration distribution. Furthermore, when examining the performance of these devices against the criteria of drug presence or absence (rather than GC/MS confirmation cutoff criteria) these devices have demonstrated positive predictive values of virtually 1. That is, a positive on-site, non-instrumented

drug test result, at least for cocaine or cannabinoids, can be relied on to indicate the presence of drug in the specimen, even though there may be insufficient amounts to be confirmed positive when using standard confirmation cutoffs.

11.2.9 Conclusions

There is no question that several of the non-instrumented drug testing devices are not only rapid and easy to use, but also are sufficiently accurate and reliable for use within a variety of criminal justice programs. There is ample peer-reviewed scientific literature supporting the accuracy of these devices as well as many studies demonstrating their utility within a wide variety of criminal justice settings. That they are being considered for use within the federally regulated workplace testing programs is also a testament to their level of scientific and regulatory acceptance. Furthermore, there is a growing body of case law addressing these devices' levels of accuracy and reliability and how they comport with various due process requirements. However, these devices will still likely need to be used with some form of confirmation testing if significant sanctions are to be imposed.

11.3 REGULATORY CONCERNS FOR POINT OF COLLECTION TESTING IN THE WORKPLACE

Michael R. Baylor, Ph.D., Craig A. Sutheimer, Ph.D., and Susan D. Crumpton, M.S.

Health Sciences Unit, Science and Engineering Group, RTI International, Research Triangle Park, North Carolina

11.3.1 Introduction

Point of collection (POC) testing is relatively new in workplace and other areas of forensic drug testing. As with laboratory-based workplace drug testing, POC test users must implement procedures that ensure accurate and reliable test results while protecting donor rights to privacy and confidentiality. Many procedures for the collection, handling, and reporting of workplace drug test specimens are common to both POC testing and laboratory-based testing. However, some aspects of POC testing are unique. These are further discussed below.

At the time of this writing, the federal government is revising the Department of Health and Human Services (HHS) Mandatory Guidelines for Federal Workplace Drug Testing Programs.^{1,2} The purpose of the Guidelines is to ensure that the regulated drug testing programs under this umbrella meet stringent forensic and scientific/technical standards. The original Guidelines addressed only laboratory-based urine drug testing. With the new Guidelines, the government plans to allow POC testing, as well as testing of other specimen matrices (i.e., hair, oral fluid, sweat). The final revised Guidelines are to be published following public comment and any revisions made after consideration of those comments.

11.3.2 POC Testing Techniques

11.3.2.1 POC Testing Devices for Drugs of Abuse

POC devices for drugs of abuse were first available in the mid-1980s and early 1990s. POC devices include both non-instrumented devices with visually detected end points as well as semi-automated or automated instrumented testing devices with instrument-read end points. POC testing can be performed in the workplace with little or no prior notice and provides information that supports decisions about hiring or continued employment. Drug tests conducted with POC devices utilize a chromatographic migration of the specimen in addition to competitive binding immunoassays, the same general scientific principle used in the initial tests conducted by certified laboratories on their regulated specimens. The devices use either a negative indicating reaction (i.e., the absence of a band indicates a presumptive positive result) or a positive indicating reaction (i.e., the presence of a band indicates a presumptive positive result). There is a wide variation in the testing panels and cutoffs available for POC devices. Although their ability to perform at some administrative cutoffs has been questioned,³ commercially available devices meet minimal technical requirements. A number of the devices have been cleared by the Food and Drug Administration (FDA). The FDA Center for Devices and Radiological Health provides information on test categorization and approval/clearance of test devices (searchable databases are available at <http://www.fda.gov/cdrh/consumer/mda/index.html#databases>).

Investigators, independent of the manufacturers, have evaluated urine non-instrumented POC devices and have found them to perform similarly to the instrumented immunoassay tests conducted in certified laboratories³⁻⁶ using current cutoffs. The investigators conducted tests on both drug-free urine and donor specimens. The drug-free urine was tested with and without drug analytes and the donor specimens were selected from specimens that had previously been analyzed and determined to be drug-free or to contain varying amounts of target analyte. Little device performance difference was noted between tests conducted by laboratory technicians and laypersons who had been trained in the proper procedures for conducting and reading the test.^{3,4}

To date, only one group of independent investigators⁷ has evaluated non-instrumented POC devices for oral fluid. In their study, fortified oral fluids at concentrations consistent with the proposed HHS cutoffs were analyzed. The study found device variability and noted device difficulty in detecting cannabinoids. The investigators suggest that the rapid evolution of the device technology should be able to overcome any current problems relating to targeted analyte and manufacturer's cutoff and be able to provide assays consistent with proposed HHS cutoffs. The investigators felt that "there is every reason to be optimistic about the future for drug testing using the oral fluid matrix."

To date, independent evaluations of instrumented POC devices have not been available for review.

11.3.2.2 POC Testing Devices for Specimen Validity

Specimen validity test (SVT) POC devices for the detection of products used to suborn urine drug testing have become more widely used in the past several years. POC devices include non-instrumented devices with visually read end points as well as semiautomated instrumented testing devices with instrument-read end points. Specimen validity tests conducted with these devices utilize colorimetric assays, the same technology utilized by certified laboratories on their instrumented testing equipment used for at least initial SVT procedures.

Both independent investigators and manufacturers have evaluated urine non-instrumented SVT POC devices for the detection of abnormal urine specimens.⁸⁻¹⁰ The studies evaluated drug-containing specimens to which were added adulterating chemicals or adulterants that had been purchased. Results from these preliminary studies were variable; however, the studies did demonstrate

the ability of the varying devices to detect creatinine, as well as some oxidizing adulterants, and to measure pH.

11.3.3 Regulatory Issues for POC Testing

11.3.3.1 Evidentiary Value

POC testing must be scientifically and forensically sound. At this time, POC test results do not meet the forensic and scientific standards that have been deemed necessary for regulated workplace drug testing. The proposed HHS Guidelines allow POC testing to identify the absence of drugs or to identify a specimen as valid. According to the proposed Guidelines, only valid negative drug test results can be reported from a POC testing site by a trained tester. All presumptive non-negative specimens must be sent under chain-of-custody to a certified laboratory for initial and confirmatory testing. A POC test specimen is considered a presumptive non-negative specimen if the POC test result is positive or invalid (i.e., a specimen with an unacceptable POC SVT result, an abnormal POC drug test response, or an abnormal physical characteristic identified by the collector or trained tester).

11.3.3.2 Regulatory Oversight

It is anticipated that monitoring POC testing would necessitate an extensive program that cannot be easily managed by a single regulatory entity. While one regulatory body could retain overall responsibility for regulated testing, it might be necessary for other organizations, designated as POC Oversight Groups (POGs), to take an active part in the direct oversight of POC testing sites and trained testers. Possible oversight groups could be the individual federal agencies under whose regulations specimens are tested, a contractor, or a nongovernment training/certifying organization (e.g., industry group). In turn, the regulatory body could monitor the POG's procedures and records.

11.3.3.3 POC Devices

Certified laboratories are expected to validate their initial and confirmatory testing instruments and assays prior to use with regulated specimens. Their validation studies address variables that exist in and among laboratories. The variables include the instruments (e.g., manufacturer, model, condition, settings), analysts (e.g., variation in practices including measurement and pipetting techniques), quality control materials, and reagents (e.g., different materials and/or mixtures, as well as differences in preparation and/or storage conditions). Due to the multiple variables, the regulatory emphasis is on the user's validation, as well as the product manufacturer's validation.

The regulatory focus on POC test validation at least in part can be shifted from the user to the manufacturer of the device. POC testing involves discrete non-instrumented devices that have fewer testing variables than the instrumented assays used by laboratories. Unlike laboratory-based instrumented tests, an individual with little or no scientific/technical knowledge and experience can utilize a POC device, without extensive training. At least two published studies have documented comparable performance between individuals with nonscientific backgrounds and those with scientific/technical experience.^{3,4} Non-instrumented POC devices are configured by the manufacturer and most include manufacturer's controls (i.e., QC integrated into the device or QC samples provided by the device manufacturer). This process should reduce variability in QC among testers, as opposed to QC samples prepared by individual users or purchased from various suppliers. POC devices require no specimen pretreatment (e.g., extraction) and no user-prepared reagents are needed for POC testing. The validation of POC devices by manufactured lot would be the basis for approved use in regulated drug testing programs.

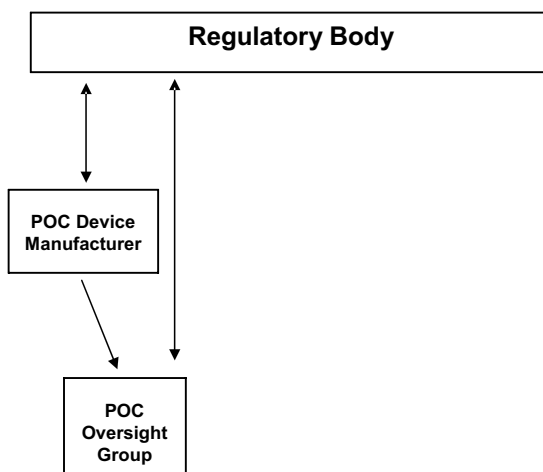

Figure 11.3.1 Regulatory Issues: POC device manufacturer, regulatory body and POG. POC manufacturer submits application and device lot validation data to the regulatory body; regulatory body forwards application and validation data to the POG for review; POG forwards PT set to the manufacturer; manufacturer reports PT results to POG for review; if acceptable the POG recommends approval of the device lot to the regulatory body; regulatory body places approved device lot on CPL.

To set some baseline level of performance, POC devices used in a regulated program must be cleared by the FDA through its regulatory processes. These processes include review and evaluation of the manufacturer's validation records for the device supporting the stated purpose (i.e., drug detection). The forensic requirements of workplace drug testing necessitate evaluation beyond that required by the FDA. This additional evaluation should involve review by the regulatory body or a POG designated by the Body.

Under this evaluation structure, the POC device manufacturer would submit an application to the regulatory body, along with data that support the manufactured lot's performance at and around specified cutoffs, as well as data supporting the lot's specificity to detect the target analyte(s) in the presence of analogous compounds. The regulatory body would forward the application and supporting data to the POG for technical review. The POG would send a performance testing (PT) set to the manufacturer. The manufacturer would report PT results back to the POG for review. If the application, validation data, and PT performance are found to be acceptable, the POG recommends approval of the device lot to the regulatory body and requests that the manufacturer submit a predetermined number of devices that could be used to assess problems that might arise during the life of the device lot. The regulatory body would issue a certificate of acceptability and place the device lot on a Conforming Products List (CPL) that would be published and updated periodically.

The relationships between the POC device manufacturer, POG, and regulatory body as described above are schematically depicted in Figure 11.3.1.

11.3.3.4 Trained Testers and POC Testing Sites

The regulatory body should specify training and performance requirements for POC testers. This training must address chain-of-custody documentation, confidentiality of test results and donor information, record keeping, and testing procedures that ensure proper operation, storage, QC procedures, result interpretation, and any maintenance procedures for each type of POC device used. Individuals should also successfully complete a set of proficiency testing samples. A certificate of qualification program would identify individuals allowed to test regulated specimens.

Individuals seeking certification for testing regulated specimens would be required to submit an application and documentation of appropriate training to the regulatory body. Qualified applicants

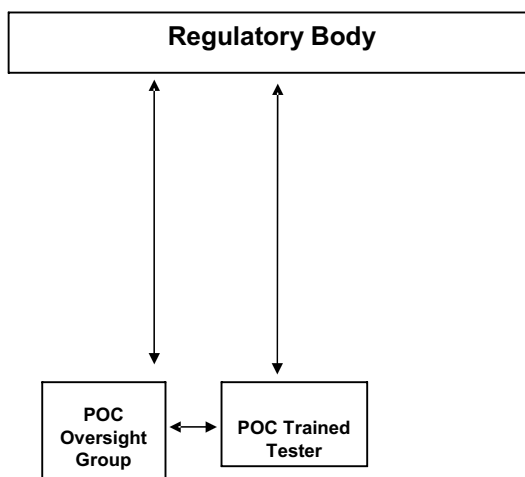

Figure 11.3.2 Regulatory Issues: POC trained testers, regulatory body, and POG. POC trained tester submits an application and training documentation to the regulatory body; regulatory body forwards application and training documentation to the POG for review; POG forwards PT set to the trained tester; trained tester reports PT results to the POG for review. If acceptable, the POG recommends certification of the trained tester to the regulatory body; regulatory body issues certificate to trained tester; trained tester provides copy of certification to the POG.

would be sent a set of proficiency samples by the POG. Individuals reporting acceptable results would be issued a trained tester certificate with a specified expiration date (e.g., 1 year). Prior to the expiration date, the POG would send a set of proficiency samples to the trained tester for certification renewal. Training records must be available for review, and should be maintained by the POG and updated as appropriate.

Ongoing compliance must also be monitored. Direct oversight of POC testing sites/trained testers could be accomplished by a POG in a manner similar to the current National Laboratory Certification Program (NLCP) for urine drug testing laboratories, with on-site inspections and PT challenges.

As is currently required of certified laboratories, the POC testing sites/trained testers must use a written standard operating procedures (SOP) manual that incorporates procedures required for regulated workplace testing. To ensure consistency among the various POC testing sites/trained testers, it may be practical for entities under whose regulations testing is performed (e.g., individual federal agencies) to write and distribute the SOP manuals.

Any procedural deficiencies or discrepant test results identified through the inspection, PT, or a specimen QA program (as described below) or reported by a Medical Review Officer (MRO) could be addressed through remediation by the POG with the POC testing site. Remediation would involve investigation and corrective actions to correct identified problems. Based on identified deficiencies, a POC testing site or a trained tester could be suspended from testing regulated specimens. Any errors attributed to a POC device itself could be referred for remediation by the POG with the POC device manufacturer. Based on identified deficiencies, a device lot could be removed from the CPL. The timing of the suspension or device lot removal would be dependent on the degree and imminence of harm to the tested population and general public.

The relationships between the trained tester, POG, and regulatory body as described above are outlined in Figure 11.3.2.

11.3.3.5 Specimens

As noted above, when the revised Guidelines go into effect, federal agencies and regulated employers will be allowed to test different specimen matrices (i.e., urine, hair, oral fluid, sweat)

in their workplace drug testing programs. These matrices are already being tested in the private sector. The choice of specimen matrix depends on several factors, especially the drug detection time using a particular specimen matrix and the reason for the test (e.g., pre-employment, post-accident, reasonable suspicion, return to duty, follow-up, random). Currently, POC devices are available for testing urine or oral fluid specimens. Devices for other specimen matrices may be developed in the future.

POC testing of urine is most suited for situations that require quick, negative results such as in emergency/crisis management. It can be used for random, reasonable suspicion/cause, and post-accident testing if drug use occurred more than 3 h prior to the incident. This type of testing may be least suited for pre-employment, return-to-duty, and follow-up testing.

POC testing of oral fluid also is most suited for situations that require quick, negative results such as in emergency/crisis management. Therefore, in a workplace setting, it is most suited for reasonable suspicion/cause and post-accident testing. It may be least suited for random testing. Oral fluid is not suited for return-to-duty, follow-up, and pre-employment testing.

11.3.3.6 Collection Sites and Specimen Collection

Specimen collection requirements should closely parallel those procedures already established for laboratory-based workplace drug testing.^{11,12} These procedures were developed to ensure a consistent, forensically defensible collection using strict chain-of-custody procedures, thereby ensuring that the integrity and identity of each specimen are maintained. A brief summary of specimen collection requirements follows.

A collection site may be a permanent or temporary facility. All sites where regulated specimens are collected must be equipped with security features limiting access to appropriate collection site personnel. A dedicated collection facility must be secured at all times. Temporary collection facilities, at a minimum, must be secured during collections.

Collection sites must tailor the facility and operations to the specimen type(s) collected. For example, oral fluid specimen collections require only direct observation. Urine specimen collections require facilities that provide donor privacy during collection and also enable observed collections. Measures must be taken to prevent specimen adulteration or substitution (e.g., turning off water supply or securing faucets, coloring the water in the toilet, preventing access to items that may be used to adulterate a specimen). All facilities must have a means for donors to wash their hands, preferably in the area where the collection takes place.

Essential elements of a proper collection include procedures for verifying donor identity; maintaining specimen identification and integrity throughout the collection process, subsequent storage, and transfers; documenting the collection and chain-of-custody using a standardized custody and control form (CCF); and examining the specimen for adequate volume and other characteristics (e.g., temperature of a urine specimen). Specimen containers should be sealed in the presence of the donor. The collection container must be tamper-evident and prevent contamination of the specimen. Some current POC devices are incorporated into the collection container. Collection site record-keeping procedures must ensure the accuracy, security, and confidentiality of drug test information.

11.3.3.7 POC Testing Procedures and Reporting Results

POC testing differs from laboratory-based testing in that the same individual may collect and test the specimen. To avoid confrontation, testing should not occur in the presence of the donor and the collector should not reveal any test results to the donor.

Presumptive non-negative specimens should be resealed with tamper-evident tape to ensure the integrity of the specimen. Both primary and split specimens should be placed into secured temporary

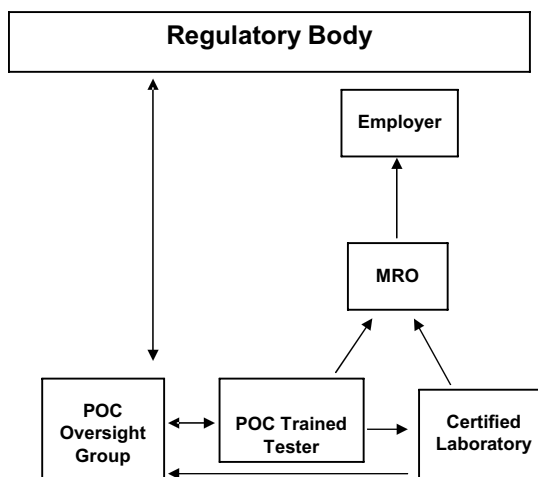

Figure 11.3.3 Regulatory Issues: POC non-negative confirmation testing, reporting results and quality assurance. Trained tester reports negative results to the MRO; trained tester forwards non-negative specimens to the laboratory for confirmation testing; a percentage of negative specimens are forwarded to laboratory for QA testing; laboratory reports non-negative results to the MRO; laboratory reports QA results to the POG; MRO reports results to the employer.

storage and be under chain-of-custody until the specimen is transferred to a certified laboratory for initial and confirmatory testing.

Specimens with negative POC drug test results and acceptable responses for POC specimen validity tests should be reported by the trained tester directly to the MRO. These specimens should be discarded immediately after testing (unless the negative specimen is to be sent to a certified laboratory for QA purposes). Valid negative results must be reported to the MRO by sending a completed CCF or electronic report. Measures must be taken to ensure the security and confidentiality of donor information.

The relationships between the trained testers, laboratory, MRO, and POG for reporting results from POC sites are depicted in Figure 11.3.3.

11.3.3.8 Quality Control/Quality Assurance

Due to the forensic aspects of workplace drug testing, QC requirements for workplace POC testing will be more stringent than those for nonregulated on-site testing in clinical environments (i.e., “point of care testing”).¹³ However, quality control requirements for POC testing will also differ from those required for laboratory-based instrumented tests in a regulated workplace testing program.

Certified laboratories are required to document the validity of specimen results in each initial and confirmatory test batch by analyzing a specified type and percentage of QC samples. POC testing using discrete POC devices has fewer testing variables. In addition, many, if not most, devices include a test line or control line that indicates proper test performance. Therefore, it would appear sufficient to document acceptable performance for each trained tester on each day that the individual tests specimens with a specific test device. As previously noted, POC testing will be used only as a screening test, with any presumptive non-negative specimens tested and confirmed in a certified laboratory in accordance with stringent QC policies.

The HHS Mandatory Guidelines for Workplace Drug Testing Programs require federally regulated programs to have an external QA program. Federal agencies and regulated employers are required to submit blind proficiency samples to certified laboratories (i.e., a specified percentage of the donor specimens they submit for testing) to demonstrate the laboratory’s ability to obtain and report results correctly. A QA program for POC testing sites/trained testers could require a

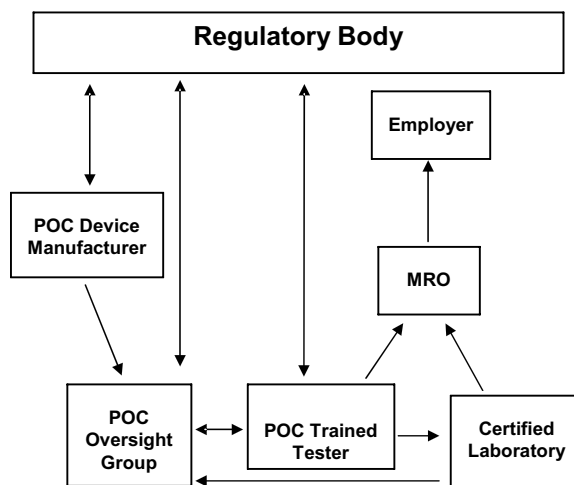

Figure 11.3.4 The regulatory oversight of POC testing: The interaction of all components.

specified percentage of POC test-negative donor specimens to be sent to a certified laboratory for testing (with donor identification and demographic information redacted). The laboratory would then report its results to the POG for review.

This QA process involving the interactions of the trained tester, laboratory, and POG is incorporated into Figure 11.3.4.

11.3.4 POC Testing Advantages and Disadvantages

The major advantage of POC testing is the almost immediate identification of negative test results. POC testing is performed as a discrete analysis, not requiring batch configuration, so individual specimens can be analyzed without delay.

Employer costs for negative POC test specimens are comparable to costs of laboratory-based testing. Due to the additional testing performed, it would appear that the employer costs for non-negative specimens will be greater than current costs for laboratory testing. POC test devices have a shelf life of 12 to 18 months. This relatively short time may be a major disadvantage to testing sites with a limited specimen volume to be analyzed, as the tendency of manufacturers to package devices in multiples could result in numbers of the devices expiring before use.

Another disadvantage of POC testing may be the fees associated with the complex oversight/regulatory program needed for an extremely decentralized population of sites/testers.

Procedural disadvantages that have been noted for POC testing in other fields, such as clinical testing,¹⁴ would not appear to be of concern in a regulated workplace setting with POC testing used only as a presumptive test method. For example, the potential for misinterpretation of results would be unlikely. A POC device that is prone to inconclusive results probably would not meet criteria for placement on the CPL. Additionally, training requirements for testers and regulatory oversight as previously described (e.g., proficiency testing, QA program using POC test-negative specimens) should reveal systemic problems.

11.3.5 Role of the Medical Review Officer

The MRO plays an essential part in regulated workplace drug testing. In POC testing, the MRO would provide the final interpretation of test results and serve as the liaison among the various parties involved in a drug test (e.g., the regulatory body, federal agency, the employer, the donor, the collection site, the POC testing site and POC trained tester, and the laboratory). The MRO must report negative

drug test results from a POC testing site to the employer/agency in the same manner as results obtained from a laboratory. Non-negative specimens must be treated by the MRO in the same manner regardless of whether they were first tested using POC tests or tested only by a laboratory.

MROs must be knowledgeable about the capabilities of the POC tests and laboratory-based test methods that were used for specimens that they review. The MRO must report any discrepant or erroneous test results to the regulatory body, so an investigation can be conducted to identify and address the cause of the problem.

Due to conflict of interest concerns, some relationships between MROs and certified laboratories are considered inappropriate and are prohibited (i.e., the MRO must not be an employee, agent of, or have any financial interest in a certified laboratory). Similar prohibitions should be instituted for the relationship between MROs and POC device manufacturers and for the relationship between MROs and POC testing sites for which the MRO reviews drug test results.

11.3.6 Regulatory Oversight

The unique challenges for the regulatory body are that the POC testing sites may be numerous and decentralized and that many trained testers may have little forensic background or training. As proposed, another oversight group (POG) could provide administrative and technical support to a regulatory body. It is conceived that delegated functions could include reviewing and approving POC devices, providing training (i.e., initial training for users or “train-the-trainer” courses), and maintaining administrative oversight of testers and POC testing sites. Records are an essential component in any forensic field. A POG could maintain the records for workplace drug testing programs such as a registry of trained testers, records of results by tester for each device as part of a QA program, and other documentation demonstrating the acceptability of testing, reporting, and record keeping.

POC testing has both technical-scientific issues and administrative-policy issues that need to be incorporated into the regulatory process.¹⁵ The Substance Abuse and Mental Health Services Administration and the Department of Health and Human Services (SAMHSA/HHS) currently certifies laboratories to perform federal workplace urine drug testing and monitors federal workplace drug testing through the National Laboratory Certification Program (NLCP) via on-site inspections and quarterly PT challenges. Similar direct oversight may be required to ensure that regulated workplace drug testing using POC testing is conducted with the equivalent integrity and technical standards as testing in a certified laboratory. With proper safeguards and regulatory oversight in place, it is envisioned that POC testing has the potential to become a significant part of regulated workplace drug testing.

Acknowledgments

The authors express their appreciation to Donna M. Bush, Ph.D., Walter F. Vogl, Ph. D., and Charles LoDico, M.S. (Division of Workplace Programs, Center for Substance Abuse Prevention, SAMHSA) for regulatory insight and to Robert Dow (RTI staff member) for graphic and editorial support.

11.4 ALCOHOL DETERMINATION IN POINT OF COLLECTION TESTING

J. Robert Zettl, B.S., M.P.A., DABFE

Forensic Consultants, Inc., Centennial, Colorado

The section covers five topics: general considerations; pharmacology and toxicology of alcohol; organizational policies and procedures for specimen collection and testing; governmental regulations; and devices for testing of breath, saliva, and urine. A comprehensive discussion of alcohol pharmacology and toxicology and evidentiary breath testing can be found in other sections of this text. The material presented in those areas serves to assist the reader in understanding this chapter.

Devices used for human subject alcohol determination can be separated into four broad categories: (1) law enforcement — driving under the influence (DUI); (2) diagnostic for treatment or other medical purposes; (3) pre-employment and workplace for compliance; and (4) for cause and random for governmental compliance. This chapter focuses on devices used in the last two venues.

11.4.1 General Considerations

The primary focus of this section is alcohol point of collection test devices and procedures, but it is appropriate to discuss briefly how and why alcohol testing is important in point of collection testing.

According to information from the National Highway Traffic Safety Administration, there were 41,471 motor vehicle traffic fatalities in the U.S. in 2000.¹ Of those 41,471 fatalities, 15,935 or 38.4% were alcohol related. This represents an average of one alcohol-related fatality every 31 min.

The National Safety Council² estimates the economic loss to society from a single highway fatality to be \$90,000, and the corresponding total economic loss exceeding \$4 billion annually.³ The drinking driver affects every one of us through increased taxes for additional law enforcement needs, medical facilities, incarceration, rehabilitation, social security and welfare for survivors, as well as increased insurance rates.

In the U.S., alcohol accounts for two thirds of all workplace substance abuse complaints and depletes a similar percentage from their health care benefit budgets. The results of a 2002 study⁴ released by the Substance Abuse and Mental Health Services Administration (SAMHSA) showed drug use trends in the U.S. Of interest is that most alcohol and drug users are employed.

Alcohol abuse and its related problems cost society many billions of dollars each year.⁵⁻⁸ Estimates of the economic costs of alcohol abuse attempt to assess in monetary terms the damage that results from the misuse of alcohol. These costs include expenditures on alcohol-related problems and opportunities that are lost because of alcohol. In a 1985 cost study, Rice and co-workers⁹ estimated that the cost to society of alcohol abuse was \$70.3 billion. By adjusting cost estimates for the effects of inflation and the growth of the population over time, that cost today could be well over \$100 billion.

11.4.2 Pharmacology and Toxicology of Alcohol

Alcohol is commonly ingested orally and passes from the mouth, through the esophagus, into the stomach, and then into the small intestine. From here, alcohol is absorbed into the blood and distributed by the circulatory system to all parts of the body. As alcohol is transported through the body by the blood flow, it passes through the liver, which is primarily responsible for its metabolism, then to the kidneys where it is eliminated into the urine, then to the brain where it elicits its primary effect, and finally to the lungs where some alcohol passes unaltered out of the body. This unaltered alcohol permits the determination of a breath alcohol concentration (BrAC) from the alveolar or deep lung air.¹⁰

Alcohol is a low-molecular-weight organic molecule that is sufficiently similar to water to be miscible with water in all proportions. In addition, alcohol is able to cross cell membranes by a simple diffusion process; therefore, it can quickly achieve equilibrium throughout the body. The result of these properties is that alcohol rapidly becomes associated with all parts of the body, *including oral fluid*, and concentrations of alcohol will be found in proportion to body water content.

11.4.3 Organizational Policies and Procedures

11.4.3.1 Collection and Testing

Although it is the quantity of alcohol present in the brain that actually affects a person's normal functions, practicality necessitates a specimen that is in equilibrium with the brain be used to reflect alcohol concentration.

Therefore, most studies center on the use of blood to correlate the degree of alcohol impairment; however, over the last 30-plus years, breath testing has supplemented blood as the specimen of choice. Due to the difficulty in the collection of urine, its use as a specimen has fallen into some disfavor. Blood is more likely to be used in defining driving under the influence of alcohol and blood and/or urine in defining driving under the influence of drugs.

Serum or plasma is often used in clinical situations where alcohol is tested. Since the water content of serum or plasma is greater than that of whole blood, serum/plasma alcohol concentrations are typically 10 to 20% greater than the corresponding blood specimen. Therefore, if serum/plasma tests are to be utilized where blood alcohol concentrations (BACs) define legal penalties, the serum/plasma concentrations must be corrected. Serum to blood ratios vary from 1.12 to 1.17 while plasma averages 1.18. A ratio of 1.16 is commonly used to make the conversion.¹¹

Blood or urine is seldom used in alcohol point of collection testing (APOCT) because of difficulties that hinder their ease of collection. In most instances, existing regulations or statutes will dictate the choice of specimen. At present breath and saliva are the specimens collected in the majority of APOCT venues.¹²

11.4.3.2 Specimens for Analysis

The most commonly used specimen for APOCT is breath for the two venues covered in this chapter: (a) pre-employment and workplace for compliance and (2) for cause and random for governmental compliance. With recent technological advances, saliva is taking on a new dimension and is pressing breath as the “new” specimen of choice. Saliva can, with appropriate care in specimen procurement and application of the accepted distribution ratios, be correlated with blood and a blood alcohol equivalent can be reported.

11.4.4 Breath Testing for Alcohol

11.4.4.1 Principles

Breath tests to determine the alcohol concentration present in a person’s body are by far the most frequently utilized tests in cases involving driving under the influence of alcohol. States today have universally adopted legislation that permits reporting of a subject’s alcohol concentration in breath units of alcohol per 210 L of breath. Breath alcohol analysis is the method of choice of law enforcement and many others due to ease and operational simplicity of new generation breath testing equipment, speed with which analyses may be conducted, convenience of being able to perform the analysis at or near the scene of an incident, and the convenience of having the subjects’ test results immediately available. (A complete discussion of breath alcohol testing can be found elsewhere in this volume.)

11.4.4.2 Breath Alcohol Testing Devices

Introduction

The National Highway Traffic Administration has established a conforming products list for instruments that conform to the “Model Specifications for Devices to Measure Breath Alcohol.”¹³ This list contains all devices currently approved to perform breath alcohol testing within the U.S. Although many of the devices found on the present conforming products list are no longer manufactured, many are still in use.

In 1995, Zettl in conjunction with the Colorado Department of Public Health and Environment conducted a national survey of alcohol programs.¹⁴ Some “electronic” devices listed in the 1995 Colorado Department of Public Health survey are no longer manufactured and newer-generation devices have been introduced since that survey was completed. Refer to the National Highway Traffic Administration conforming products list for a complete listing of all “electronic” instruments that can be used for point of collection testing.

Electronic Devices — Evidentiary

Electronic devices are generally classified into two distinct categories: (1) tabletop devices, which are larger and more expensive units originally designed for use in DUI testing, and (2) handheld or preliminary breath (alcohol) testers (PBTs), which are smaller units originally designed for use as screening devices by law enforcement to determine a suspected DUI’s approximate

BrAC level at the time of stop. PBTs are now used extensively as evidentiary units in workplace and DUI testing.

Both types of devices are designed to analyze a breath sample and determine the amount of alcohol present in such a manner that the results have a degree of scientific accuracy and specificity sufficient to be reliable for presentation in court as evidence. They are self-contained portable laboratories in which the underlying principle, mode of operation, and safeguards are such that the end user can effectively operate the instruments and develop reproducible results.

Electronic Tabletop Devices

Infrared (IR) technology utilizes the principle that alcohol present as a vapor in breath absorbs specific wavelengths of IR light. Alveolar air is trapped in a sample chamber. IR light is directed through the sample cell and finally reaches a detector that measures the amount of light absorbed. As the concentration of alcohol vapor increases in the chamber, the amount of IR energy reaching the detector falls in a predictable exponential manner; hence, IR devices measure alcohol by detecting the decrease in the intensity of IR energy as it passes through the chamber.

The Draeger Corporation, Breathalyzer Division (Durango, CO) and Intoximeters, Inc. (St. Louis, MO) have developed breath test instruments that incorporate IR technology combined with an electrochemical (EC) fuel cell. Use of dual technology enhances both the quality and integrity of the sample and the accuracy of the alcohol test result. Fuel cell technology is discussed later in this chapter under Electronic Handhelds.

The most recent device, the Intoxilyzer 8000, uses dual IR (two separate wavelengths), one for alcohol concentration and the other for interferent detection.

Electronic Gas Chromatographic Tabletop Devices

These devices are no longer being manufactured but may still be in use. They are the Gas Chromatograph Intoximeter (GCI) Mark II and Mark IV manufactured by Intoximeters, Inc. and the Alco-Analyzer Gas Chromatograph, models 1000, 2000, and 2100, manufactured by Luckey Laboratories and later US Alcohol Testing.

Although the instruments used different methods of detection, they were of equal specificity and accuracy. They could be used as either direct measurement devices or they could analyze collected samples such as blood, delayed breath, saliva, and urine by means of headspace chromatography. They were excellent for use in a centralized facility setting; that is, samples could be collected in the field and forwarded to a centralized processing facility where technical personnel conducted the testing.

Electronic Handheld Devices: PBTs

Handheld “electronic screening devices” are small, portable, relatively inexpensive, may cost only a few hundred dollars, and were originally designed to estimate the BAC or BrAC of an individual. Some of the devices may be prone to erroneous readings both falsely high and low. The electrical sensor instruments — fuel cell — are generally more accurate ($\pm 10\%$ range or better) and some are more specific for alcohol than others with printer attachments to be used in evidential settings. As stated, they were originally intended to assist in quickly determining the approximate alcohol concentration in an individual and were referred to as PBTs. The devices are useful for monitoring and controlling alcohol abuse and or intoxication in various workplace, alcohol abuse programs, and correctional institutions.

Evidentiary handhelds utilize an EC sensor — generally a fuel cell — to measure the amount of alcohol present in the sample. All of the devices in this category use alveolar air and may be calibrated for BrAC concentration.

Table 11.4.1 Pass–Warn–Fail PBTs

-
1. B.A.T. III by Century Systems, Inc. uses catalytic combustion for alcohol analysis. Pointer indicates Warn or Fail.
 2. Alcohalt Detector by Mine Safety Appliance Company uses catalytic combustion for alcohol analysis and two indicator lights for Pass or Fail.
 3. A.L.E.R.T. Model J3AD by Alcohol Counter Measures, Inc. Uses a Taguchi semiconductor detector to analyze the alcohol and a series of green, amber, and red lights to indicate Pass, Warn, or Fail.
 4. Older generation Alco-Sensor by Intoximeters, Inc. Used a cluster of light-emitting diodes to indicate Pass, Warn, Fail (later models use a digital display for a direct readout of the % alcohol present).
-

Table 11.4.2 Digital Display PBTs

-
1. Alco-Sensors II through IV by Intoximeters, Inc. The Alco Sensor IV is shown in Figure 11.4.1.
 2. Phoenix by Life Loc. See Figure 11.4.2.
 3. CMI Corporations S-D2 and Models 200, 300, and 400. See Figure 11.4.3 for the S-D2.
 4. National Draeger's Alcotest 7410. See Figure 11.4.4.
-

Because the devices were originally intended for screening, they should be used carefully and only for their intended purpose by trained personnel. Some of the older-generation devices are not sufficiently accurate for evidentiary purposes and if the subject tested is placed at risk pending the results of such tests, then the initial “screening” test should be confirmed by an evidentiary test. PBTs are extremely useful because they are generally less expensive than tabletop units and training and upkeep is less involved. Newer-generation PBTs, when used according to manufacturer specifications, can yield an accurate BrAC.

Pass–Warn–Fail Devices

These devices are calibrated to determine into which of three likely broad-range categories of BrAC an individual will likely fall.

PASS — Alcohol concentration below a predetermined level. Usually a level at which the individual is considered able to drive safely. Usually less than 0.05% except for underage drinkers.

WARN — Alcohol concentration above the level where a person would pass but below a level where the individual is considered intoxicated. Usually at or above 0.05% but less than the state's legal limit for per se.

FAIL — Alcohol concentration above the level where the individual is considered intoxicated. Usually at or above 0.08% or 0.10%. Depends on the state's level for DUI.

The concentrations at each level may be arbitrarily set as desired. Refer to Table 11.4.1 for a listing of some of the Pass–Warn–Fail devices and Table 11.4.2 for a listing of some of the digital display devices.

Digital Display Devices

There are many digital display devices on the NHTSA conforming products list. Some are shown in Table 11.4.2 (Figures 11.4.1 through 11.4.4). All use a fuel cell to determine the amount of alcohol present and %BrAC is digitally displayed.

Handheld — Non-Evidentiary

According to the manufacturer's product information the Alco-Scan Model AL-2500 (Figure 11.4.5), is a very versatile device that measures %BAC. The user gently blows at the sensor's intake and within 2 s the LCD displays a BrAC. The AL2500 is a compact and ideal device for use in social gatherings and for group testing.¹⁵

Figure 11.4.1 Intoximeters, Alco Sensor IV.

Figure 11.4.2 Lifeloc, Phoenix.

Figure 11.4.3 CMI SD-2.

Figure 11.4.4 Draeger 7410.

Figure 11.4.5 Alco-Scan Model AL-2500.

There are many devices like the Alco-Scan Model AL-2500, many priced under \$100, but the end user should be cautioned that many are non-evidentiary and may not be suitable for some testing venues.

Screening Devices

NHTSA establishes which devices can be used as screening devices under its “Conforming Products List of Screening Devices to Measure Alcohol in Body Fluids.”¹⁶

11.4.4.3 Saliva-Based Technology

Analytical Principle

Saliva collection for alcohol testing is regularly employed in POCT facilities but is not used in DUI testing due to its practical constraints in court. Although saliva may be impractical for DUI enforcement because significant subject cooperation is needed to facilitate collection, recent advances in collection technology hold great promise for its use in POCT on-site (roadside) drug detection. For additional information, visit the RoadSideTestingAssessment Web site.¹⁷

Saliva alcohol results can be compared to the amount of alcohol contained in a person’s blood. If collected properly by observing a waiting period after a person has consumed his or her last alcoholic beverage, usually 10 to 15 min, then any residual alcohol will have been absorbed, swallowed, or evaporated, and the person’s mouth is “clear.” According to one manufacturer’s

information the relationship between the amount of saliva alcohol and blood alcohol is 1:1 whereas with breath it is 000048:1, making saliva a more sensitive testing medium than breath.¹⁸

There are two prominent saliva-based alcohol test procedures. The QED saliva alcohol test procedure will not react with ketones often found in the saliva of patients with diabetes. Unlike some breath analyzers and other saliva tests, the QED is specific to ethyl alcohol and will not cross-react with acetone and ketones produced by diabetics.

The second type of disposable tester, strip test technology, does not have a great correlation between a person's true BAC and saliva alcohol concentration. Strip-based saliva testers are treated with an enzyme alcohol oxidase, which responds to alcohol in proportion to the concentration of alcohol in a mixed saliva sample placed on it. The user estimates the BAC by comparing the color change on the test strip patch to standard colors calibrated to correspond to different BACs. Although some saliva testers seem to indicate the presence of alcohol well, the enzyme alcohol oxidize used in these testers is easily affected by hot and cold temperatures. Hot temperatures will tend to indicate falsely high readings, while cold temperatures will tend to indicate falsely low readings.

Exposure to temperatures above 80°F or to ambient air will destroy the enzyme alcohol oxidase, rendering the tester useless. Most saliva testers give no indication if contamination has occurred, and if it has, they may not work effectively. Saliva testers generally have a shelf life of 1 year or less.

The technology and chemical reaction employed in the QED or the test strip technology is not as precise, accurate, or reliable as breath alcohol testing. Saliva-based alcohol tests require an evidential breath test (EBT) to confirm positive test results. Saliva alcohol testing is much less expensive to operate than a breath test, and unless a POCT facility conducts a very high volume of tests in a central location, then saliva testing instead of breath may be more cost-effective. Since most employees do not test positive for alcohol, simple screening is generally more cost-effective for POCT facilities.

Saliva-Based Devices

QED Saliva Alcohol Test — The QED (Figure 11.4.6) is a quantitative test device for the rapid determination of equivalent BAC using a non-invasive saliva sample. Approved by the Federal Department of Transportation (DOT) for commercial alcohol testing programs, the QED uses a unique patented lateral flow method to rapidly determine alcohol presence in saliva expressed as %BAC and milliliter per deciliter concentration. It is as simple as reading a thermometer.¹⁹

The QED Saliva Alcohol test uses a preset chemical reactive process that requires no user intervention; a color bar rises to the level of alcohol present in the system in much the same way as a mercury thermometer. In extensive clinical trials, saliva alcohol levels measured by the QED

Figure 11.4.6 QED Saliva Alcohol Test.

Saliva Alcohol test demonstrated a high correlation rate of 98% ($r = 0.98$) to blood analyzed by sophisticated laboratory gas chromatography methods.²⁰

The QED Saliva Alcohol Test (Figure 11.4.6) is an easy-to-use diagnostic procedure with everything required contained in a sealed foil package. Total time required for the test is between 3 and 5 min. The three basic steps are as follows:

1. Using the cotton swab included, actively swab around the cheeks, gums, and tongue for 30 to 60 s or until the cotton swab is completely saturated with saliva.
2. Place the test device on a flat surface. Gently twist the swab with the collected saliva sample into the entry port and apply steady pressure to activate the capillary action until the pink fluid passes the QA Spot™ located at the top of the test device.
3. Allow the test device to develop for 2 min. A distinct purple bar will form within the marked scale region. The highest point of the purple bar represents the level of alcohol expressed either as a percentage or as grams per 100 ml or milligrams per deciliter concentration.

According to product information, the QED Saliva Alcohol Test will accurately measure a range of BAC of 0 to 145 mg/dl or 0.000% to 0.145% equivalent BAC.²⁰

POCT facilities using the saliva alcohol test in very remote areas can comply with the DOT requirement that confirmation tests on positive screening tests must be conducted within 30 min. DOT will accept results of confirmation tests conducted more than 30 min after a positive screening test (49 CFR Part 40 section 40.65, paragraph (b)).²⁰ The DOT added a sentence, which directs the Breath Alcohol Technician (BAT) to simply explain “why?” if a confirmation test is done more than 30 min after a screening test.

Saliva-Based Test Strip — Alco-Screen: The ALCO-Screen™ (Figure 11.4.7) saliva alcohol test is intended for use as a rapid, highly sensitive method to detect the presence of alcohol in saliva and to provide a semiquantitative approximation of BAC. For applications where a quantitative determination of BAC is required, a positive ALCO-Screen result must be verified using an acceptable quantitative alcohol analysis procedure. ALCO-Screen requires no special training provided instructions are followed carefully. However, a qualified professional should perform

Figure 11.4.7 ALCO-Screen.

quantitative follow-up testing. ALCO-Screen is not intended as a measurement of mental or physical impairment but rather a screening test for the presence of alcohol in semiquantitative amounts. As with any saliva-based or breath alcohol tester, a deprivation period of at least 15 min must be observed before beginning the test. This includes non-alcoholic drinks, tobacco products, coffee, breath mints, food, etc. The ALCO-Screen is used by saturating a reactive pad with saliva from the test individual's mouth or sputum cup. At exactly 2 min, a change in color is observed in the reactive pad. A color change of green or blue indicates the presence of alcohol and a positive result. Results obtained after more than 2 min and 30 s (2.5 min) may be erroneous and should not be used. A BAC is estimated by comparing the color of the reactive pad to the color chart on the back of the test package (Figure 11.4.7). The ALCO-Screen produces a color change in the presence of saliva alcohol ranging from a light green-gray color at 0.02% BAC to a dark blue-gray color near 0.30% BAC. ALCO-Screen is designed and calibrated to be interpreted 2 min after saturation of the reactive pad. Waiting longer than 2 min to interpret the test can result in erroneous or false-positive results. ALCO-Screen is a visually interpreted test; as such, exact interpretation of results is not required in most cases. However, persons who are color blind or visually impaired may experience difficulty when a more specific interpretation is required. Furthermore, where test interpretation may be biased for whatever reason, it is suggested that another person's opinion of test results or color matching be obtained.²⁰

ALCO Screen 2: ALCO-Screen 2 is a simple and cost-effective method of monitoring for alcohol consumption in a zero tolerance testing program. According to its product information, the ALCO-Screen 2 has been tested and approved by the U.S. DOT for required testing of all transportation and safety-sensitive employees for BACs above the federally mandated zero tolerance level of 0.02% (Figure 11.4.8). ALCO-Screen 2 is a simple one-step saliva-screening test that works in a clean, non-invasive manner and provides results in 4 min. Simply wet the test pad with saliva and wait 4 min. The development of a line on the test pad at 4 min indicates a BAC exceeding 0.02%. Any line, no matter how faint, developing on the reactive test pad at 4 min is a positive

Figure 11.4.8 ALCO-Screen 2.

test. The Alco-Screen 2 is highly sensitive and can be used for evidentiary purposes. Completed test results can be photocopied for permanent filing.²⁰

11.4.4.4 Chemical–Color-Change-Based Devices

Subcategories of screening devices, which are not electronic, make a determination of alcohol concentration by use of a chemical reaction. The first type of non-electronic device consists of either dichromate or permanganate salts in acid-impregnated crystals, which are placed in glass tubes. The individual being tested blows into a balloon or plastic bag or through the tube. After a certain volume of air or time has transpired, a measurement of the length of stain on the crystals in the tube (color change) is used to approximate the BrAC. The color change is a result of the chemical reaction occurring between alcohol and the chromate or permanganate salts in the crystals. Examples of older devices of this type include the Alcoalyzer, several varieties distributed by Intoximeters, Inc., the Becton-Dickinson devices, Kitigawa Drunk-O-Tester by the Komo Chemical Industrial Company, Sober-Meters (Mobats) by US Alcohol and AlcoPro (Knoxville, TN). These screening devices use a mixed expired breath sample with the exception of the Becton-Dickinson device, which uses a two-chambered plastic bag to obtain alveolar air for the screening test. The results obtained from using these devices should be read according to time requirements expressed by the manufacturer. Other oxidizable components of breath will continue to react with the chemicals and may produce false positives.

Screening devices that utilize a color change reaction for alcohol detection are disposable and good for only one test whereas electronic devices have an extended life and can be used repeatedly after resetting; hence they may be more cost-effective if an agency is doing multiple testing.

One of the more popular disposable screeners is the BreathScan® Alcohol Detector (Figure 11.4.9).²⁰ According to the manufacturer's promotional material, "it is a disposable breath-alcohol indicator designed for one-time use" and according to its manufacturer it provides an accurate measure of the alcohol present in the exhaled breath of a test subject. By measuring the alcohol content in the breath, a reliable indication of the blood alcohol level is achieved. The BreathScan detector employs a new, patented technology for simple, on-the-spot screening for the presence of alcohol. The BreathScan tester can only be used once and then disposed of, minimizing contamination associated with repeated use of nondisposable units (no AIDS cross transmission).

The BreathScan's low cost and ease of use make the tester ideal for screening to determine whether an individual should submit to a forensic-quality blood test for confirmation. Just break the internal capsule, shake, and blow hard into the test cylinder of breath alcohol detector for a few seconds. Then read the color change of the chemical crystals in 2 min or less. Approved by the DOT, the detectors are available in five BAC levels for a complete range of sensitivity: 0.10%, 0.08%, 0.05%, 0.04%, and 0.02% (for zero tolerance testing), and they are very light and easy to carry around, weighing 0.16 oz each.

Figure 11.4.9 BreathScan Alcohol Detector.

Figure 11.4.10 PAS IV “Sniffer.”

11.4.4.5 Passive Alcohol Sensor Devices

“Passive” alcohol sensing (PAS) devices are designed to detect the presence of alcohol in a person’s normally expelled breath; that is, the subject being tested is not required to blow into a mouthpiece as with conventional breath test devices. Passive alcohol sensing devices pull, through the use of a fan or other mechanical means, the vapor from the subject’s normal breathing when the device is activated and held in close proximity to the subject’s mouth. The device can also be held over open containers of an alcohol beverage to see if an underage person is drinking illegally. The present distributor of the PAS Systems is LLC (Fredericksburg, VA). It markets the PAS III, non-invasive alcohol-screening instrument, which has a built-in high-intensity flashlight (Figure 11.4.10). Their product information refers to the device as a “sniffer” for overt or covert alcohol detection. This device uses fuel cell technology for determining alcohol concentration. Another PAS device, the Alcometer, is currently available from Lions Laboratories (Cardiff, Wales, U.K.).

Passive alcohol sensors have had a varied history — first introduced in the early 1970s without much success. In a recent DOT/NHTSA study (DOT HS 807 394), one such device was able to discriminate among differing alcohol air samples under laboratory conditions. The user has to be cognizant that passive alcohol sensors are influenced by wind disturbances. Wind or any air movement tends to invalidate their proficiency.

11.4.5 Blood and Urine — Collection, Identification, and Preservation of Specimens

This issue is addressed only briefly here. Other treatises and handbooks can be found that will assist the reader in understanding this area of alcohol testing.^{21,22} Blood or urine specimens must be collected in a manner to maintain the chain of custody as in any other forensic case. However, additional precautions are required since the specimens are biological in nature, namely, removal of blood by qualified medical persons in an alcohol-free manner, and preservation of the specimen to permit mailing and long-term storage. Before establishing a system for collection, one should consult with the certifying state or other agency in control of specimen collection and testing to prevent unnecessary problems.

11.4.6 Quality Assurance and Proficiency Testing

11.4.6.1 Saliva

Quality control (QC) requirements for the Saliva Alcohol test can be conducted using control checks, with the Saliva Alcohol Ethanol Control from OraSure Technologies.²³ Saliva alcohol ethanol control solutions should be run once per lot number of saliva alcohol tests.

Saliva-based devices such as the ALCO-Screen may be qualitatively verified using a test solution prepared by adding 4 drops of 80-proof distilled spirits to 8 oz (1 glass) of water. This solution should provide a color reaction equal to or higher (darker) than the 0.04% color block. The color reaction with alcohol in saliva is somewhat slower and less intense than with alcohol in aqueous solutions.

11.4.6.2 Body Fluids

A laboratory conducting blood alcohol determinations whether for clinical or forensic purposes should maintain an internal system designed to assure the reliability of all laboratory data and should participate in an external proficiency testing program, where available, that evaluates the laboratory on the basis of the comparability of its results with those of several reference laboratories analyzing the same sample.

The quality assurance program should include maintenance and periodic testing of equipment, validation and recalibration of methods, reagent evaluation, and surveillance of results. In-house reference calibrators and controls may be prepared from outdated whole human blood targeting concentrations of 0.000, 0.050, 0.100, 0.200, and 0.400% ethanol. Various reference materials are available to prepare or serve as standards, calibrators, and controls, e.g., the National Institute of Standards and Testing (NIST) material, SRM 1821 Ethanol (formerly National Bureau of Standards), and the College of American Pathologists (CAP) alcohol reference materials. Many states, private entities, and reagent manufacturers provide reference, calibrator, and control materials.

For standardization, calibrators are assayed in triplicate and an appropriate standard curve prepared. Standardization should be repeated periodically or as dictated by changes in operational protocol. One or more quality control blood specimens (0.080, 0.015%, etc.) should be prepared and the mean and standard deviation determined for a total of 20 samples analyzed over a period of 10 days. The quality control sample should then be analyzed with every run of unknown alcohol samples and the result should fall within 95% confidence limits. The American Academy of Forensic Sciences, Toxicology Section and the Society of Forensic Toxicologists, Inc. have approved a quality assurance program titled, "Forensic Toxicology Laboratory Guidelines."²⁴

These same quality control procedures should be used for the testing of any other body fluids such as urine, serum, saliva, and post-mortem samples. An excellent resource for quality assurance can be found in Garriott's *Medicolegal Aspects of Alcohol*²² or by obtaining the "Forensic Toxicology Laboratory Guidelines" from the American Academy of Forensic Sciences, Toxicology Section or the Society of Forensic Toxicologists, Inc.²⁴

Duplicate aliquoting and testing of forensic biological specimens is an important part of any quality assurance procedure or program. In general, the results of the two independent tests should fall within a range of each other by $\pm 10\%$ or 0.02% BAC. Other accuracy or precision criteria may be used, but an increased degree of confidence in the reported results is achieved by duplicate testing.²⁵

11.4.6.3 Breath

Although correlation between alcohol concentrations calculated using breath testing instruments and alcohol concentrations determined directly from blood have been well documented in the literature and accepted by the courts, it is necessary to have a method for the standardization and quality control of breath test devices. For scientific and legal reasons, it is necessary to demonstrate that a particular device was functioning properly at the time a subject was tested.

Wet Bath Breath Alcohol Simulation

The relationship between the concentration of alcohol in air as compared to blood at 34°C is discussed in other chapters of this text. The partition ratio for air/blood is greater than that of

air/water; therefore, if an aqueous alcohol solution is heated to 34°C the amount of alcohol in the air space at equilibrium will be less than that of blood. To produce a breath sample that simulates a given BAC, it is therefore necessary that the aqueous (water and alcohol solution) be of an alcohol concentration greater than the expected reading value. If an expected BrAC of 0.100% at 34°C is required, then the aqueous water and alcohol concentration must be 0.121%.

Simulation Units for Breath Alcohol Testers

There are several manufactures of breath alcohol simulation devices. A complete list of companies and their devices can be obtained by contacting the National Highway Traffic Safety Administration, Office of Alcohol and State Programs, at 400 Seventh Street, S.W., Washington, D.C., 20590, (202) 366-5593 and asking for the current Model Specifications for Calibrating Units for Breath Alcohol Testers.

The Simulator maintains the temperature at a constant $34 \pm 0.2^\circ\text{C}$. The simulator contains several basic components: the first is the jar that holds the solution; the second is the head, which serves as a seal to the jar and contains the thermostat, thermometer, propeller, and motor, an air inlet tube that is attached to a bubbler tube, an air outlet tube, and a wire mesh baffle to prevent the solution from escaping through the outlet tube.

The simulator solution is the most critical component. It should be carefully prepared and its accuracy checked by a competent laboratory and standardized by chemical and chromatographic analysis, comparing the results to a primary reference standard material (e.g., potassium dichromate, NIST Alcohol Standard).

Gas Breath Alcohol Simulation

Breath alcohol simulation is achieved by using a dry gas mixture. Several manufactures prepare or sell gaseous ethanol products. The device consists of a tank of pressurized air containing a specified alcohol concentration; a button is depressed and the alcohol/air mixture is released into the breath-testing device. These gaseous standards are useful if the breath test instrument utilizes a relatively small sample volume. For breath testing instruments with large sample volumes, use of these gaseous standards may or may not be practical. Any pressurized gas mixture of alcohol and air is subject to variation due to atmospheric pressure; hence, the mixture should be standardized against a wet solution of known alcohol concentration prior to use in a field situation.

For a complete listing of the dry gas ethanol manufactures, contact DOT/NHTSA and obtain its most recent listing of these units, contained in the conforming products list of calibrating units.²⁶

11.4.7 Concluding Remarks

The abbreviation BAC refers to blood alcohol concentration, with concentrations expressed as percent weight to volume, % (w/v) or grams of alcohol per 100 ml of blood. The abbreviation BrAC refers to breath alcohol concentration expressed as percent weight to volume, % (w/v) or grams of alcohol per 210 L of deep lung or alveolar breath. The term alcohol refers to ethyl alcohol or ethanol. There are many excellent resources for forensic alcohol information; those by Garriott and Saferstein are especially helpful. In addition to printed documentation, numerous Internet sites are available. Table 11.4.3 provides a list of some of these.

Acknowledgments

The author thanks Yale Caplan, Ph.D., and the manufacturers of alcohol test equipment for providing assistance, information, and photographs.

11.5 ON-SITE POINT-OF-COLLECTION DRUG TESTING: HISTORY, DEVELOPMENT, AND APPLICATIONS

Jane S.C. Tsai, M.D.

Roche Diagnostics, Indianapolis, Indiana

The advantage or projected benefit of prompt analytical investigations near the site of specimen collection has aggrandized the development of point-of-care products in diverse fields of *in vitro* diagnostics. POC is used in clinical or diagnostic tests as an abbreviation for point-of-care testing. A variety of descriptions have been used to describe diagnostic POC testing (POCT), including on-site testing, near patient testing (NPT), and decentralized testing. The term POC is also cited in the literature for drugs of abuse testing and clinical toxicology.^{1–3} In contrast to general clinical diagnostic assays, testing for drugs of abuse involves the considerations of specimen collection, chain-of-custody, specimen validity, two-tier screening and confirmation testing, and the reporting process. Therefore, SAMHSA (Substance Abuse and Mental Health Services Administration) and

DTAB (Drug Testing Advisory Board) have adopted the term point of collection testing (POCT) for POC drug testing during the drafting process for the new “Mandatory Guidelines for Federal Workplace Drug Testing Programs.”⁴

Although both the concept and practice of POCT have been evolving over an extended period of time, technological advances in the past two decades have greatly expanded the role of POCT in health care. An assortment of POC tests, ranging from urinalysis strips to handheld sensor systems and sophisticated bench-top analyzers, are currently in active use,¹ especially for applications that require fast turn-around time (TAT). In the areas where the availability of an immediate test result could influence the outcome management or patient care, the use of POCT is desirable even though there are important considerations regarding the reliability, accuracy, and cost-effectiveness of these tests.

Testing for drug abuse or misuse is an example of areas where the immediacy of a test result could contribute to enhance the efficiency of the testing program. Therefore, POCT has been applied in workplace drug testing programs to facilitate the decision-making process^{5,6} and evaluated in the field for road-side testing or traffic safety.^{7,8} POC drugs of abuse testing is also widely used in various compliance programs (e.g., criminal justice, psychiatric, rehabilitation, and drug treatment testing) to aid in behavior modification for higher admission of use and better sanctions of ongoing drug use.^{9,10} When used appropriately, POC substance abuse testing can be utilized in clinics or the emergency department to help rule out or rule in drug exposure.^{1,3}

In Subpart L of the draft of new mandatory guidelines,⁴ POCT will be defined as “an initial test conducted at the collection site either to determine the presence of drugs and/or to determine the validity of a specimen.” The proposed guidelines specify two types of POCT devices: (1) Non-instrumented for which the end-point result is obtained by visual evaluation (i.e., read by human eye); or (2) instrumented for which the result is obtained by instrumental evaluation (e.g., densitometer, spectrophotometer, fluorometer).

The majority of publications have used the expression “on-site” instead of “POC” for drugs of abuse testing. In addition to the terms “on-site,” “point-of-care,” and “point-of-collection,” an assortment of terminology has been used to describe single-use, disposable, commercial immunoassay kits for drugs of abuse screening. Trade names that contain or imply the words “rapid,” “quick,” “fast,” “instant,” “express,” “simple,” “screen,” “scan,” “no-step,” or “one-step” have been used in commercial drug POCT products.

11.5.1 Evolution of On-Site/POC Drug Testing

During the early phases of drug testing, “on-site” urine drug tests were carried out on the premises as compared to those sent to an “off-site” laboratory. The first court-based testing laboratory was established in 1971.⁹ On-site urine drug testing using “instrumented” immunoassays could also be carried out in a clinic with immediate feedback of results to patients and staff. In 1977, Goldstein et al.¹¹ evaluated on-site vs. off-site urine testing in a methadone treatment program. The authors concluded that there were negligibly small differences between the on-site or off-site urine testing groups with respect to illicit drug use although other advantages might justify the adoption of on-site testing in methadone programs.

At the early stage of workplace drug testing implementation, the term “on-site” urine testing for drugs of abuse was generally used to refer to tests “done at the place of business.”¹² In the 1986 NIDA Research monograph 73, Willette¹² wrote that “the first major consideration” to be reviewed when selecting a system for drug testing is to decide if testing will be done on-site or by an outside laboratory. The horizon of on-site drug testing has since been expanded far beyond the defined “on-site equipment at on-site testing area” to an array of “non-instrumented” devices used by various substance abuse testing programs. In the monograph, however, the described advantages and disadvantages of on-site vs. laboratory screening remain coetaneous considerations for current on-site drug testing.

The historical milestones for the development of the federal guidelines have been for laboratory drug testing, and the drafting of guidelines that will formally permit on-site testing⁴ was still in process as of early 2004. Subsequent to the publication of the 1988 mandatory guidelines,¹³ NIDA sponsored a “Consensus Conference” in 1989 to assess and evaluate such programs and to develop recommendations for change.¹⁴ The seven working groups and the participants of this conference were able to reach a consensus as recorded in the Consensus Report.¹⁴ The issue of on-site testing was one of four issues considered by multiple working groups. In this Consensus Report, the “on-site initial screening only testing facilities” should “only be allowed where safety issues demand the most rapid turn-around time, justifying the risk to the client inherent in unconfirmed tests, and the considerable difficulties in achieving accurate testing that such facilities create.” It was agreed that on-site urine screening “can reliably identify negative specimens, provided appropriate safeguards are built into the procedure.”

A NIDA-funded evaluation of 11 laboratory-based on-site drug testing facilities¹⁵ concluded that on-site drug testing was technically possible for screening in the private sector, military, and criminal justice systems. However, recommendations were made to address the flaws identified in personnel, specimen handling, security, standard operating procedure manual, testing method, quality control and assurance programs, and policies.^{15,16} It was recommended that guidelines should be developed to establish operational consistency and analytical accuracy among on-site drug testing facilities.

Meanwhile, the 1989 Nuclear Regulatory Commission (NRC) “Fitness for Duty” rule permitted NRC licensees to have their own on-site testing program.¹⁷ Licensees were permitted to conduct initial screening tests of an aliquot before forwarding selected specimens to a laboratory certified by the Department of Health and Human Services (HHS), provided the licensee’s and testing facilities meet the stated quality criteria for conducting the tests.. Similarly, a 1991 National Institute of Justice (NIJ) study on urinalysis technology comparison reported that on-site instrumented drug testing demonstrated equal performance to commercial laboratory-based testing.^{9,18}

In parallel with instrumented testing, non-instrumented-based “on-site testing devices” that can be used without the need of a laboratory were launched into a few nonregulated drug testing fields but did not become a viable alternative of regulated workplace drug testing when the federal-mandated testing was initiated. The revision of mandatory guidelines in 1994¹⁹ also did not specify rules for on-site testing; however, several departments of the U.S. government have since sponsored evaluations and working groups to assess the reliability of, and to address issues associated with, these on-site testing devices.^{20–23} During the SAMHSA-sponsored On-Site Drug Testing Workgroup Meeting in 1999,¹⁶ the consensus recommendations from 1989 were reviewed again. It was recognized that the main elements remain the same but the “grid” would be revised to take into consideration the non-instrumented-based and instrumented-based techniques, to add oral fluids, and to leave out “elements that are clearly laboratory based.”

A laboratory for conducting “only instrumented initial drug and validity tests” will be called an Instrumented Initial Test Facility (IITF) as described in Subpart M of the draft of new mandatory guidelines.⁴ Four types of specimen can be tested at an IITF (hair, oral fluid/saliva, sweat/patch, and urine). In comparison, a POCT will be “an initial test conducted at the collection site” using either non-instrumented or instrumented assays for urine or oral fluid drug testing.

In addition to the SAMHSA mandatory guidelines for workplace drug testing, several other organizations have developed their recommended “guidelines” for forensic, athletic, or clinical drug testing. The National Academy of Clinical Biochemistry (NACB) Laboratory Medicine Practice Guidelines addressed the “major limitations” of immunoassays for drug testing in emergency department and clinical laboratories to support the diagnosis and management of the poisoned patients.²⁴ Issues associated with the nature of antibody-based drug screening and the different cutoff requirements for workplace vs. compliance or clinical testing are applied to both laboratory-based and POC drug testing. Some of the countries that develop their drug testing guidelines take into consideration the different drug testing segments. For example, the Swiss guidelines for drug

testing (non-legally binding) defined four areas of application: clinical sector, substitution or withdraw treatment, forensic investigations, and “non-traditional” environment (workplace, physicals, military, school).²⁵ The application of non-instrumental immunoassays in each of the four areas is addressed in the document; however, the use of rapid tests is generally not preferred.

Despite that on-site drug testing has not been permitted in mandated testing programs and is not preferred in many settings, there has been a significant growth of on-site drug testing in the past few years.^{16,26} Compared to off-site urinalysis, on-site drug testing was shown to have lower variable costs, and total costs were lower once a threshold of 27 employees tested was attained.²⁷ Mastrovitch et al.²⁸ evaluated the POCT screening approach in an emergency department of a tertiary-care, urban medical center and showed at least 37.5% cost saving per analyte using POCT as compared to laboratory-based urine screening. The widespread interest in on-site drug testing can also be measured from the arrays of comparative studies conducted in the past decade that evaluated various combinations of “currently available on-site drug testing devices” under a variety of conditions.^{20–23,29} The business models for on-site drug testing are very complex due to multiple customer types with multiple requirements and expectations. With few examples of federal agency preemption, on-site testing has been subject to different U.S. state laws and various levels of restrictions. The manner in which a drug testing program is managed in private sectors can be quite client-driven. The recent explosion of on-site testing products and the Internet has further complicated the fields of on-site drug testing. Therefore, the examples described in this chapter are general representations and are not all-inclusive for these very diverse fields.

11.5.2 History of Technology and Product Development

Significant strides in the development of technologies and products for competitive immunoassays of small molecules have been made in the past 30 years. There have also been substantial research and development investments in drug screening technologies. Generally, the instrumented immunoassays played a role in supporting the commercialization of non-instrumented immunoassays. One example of such can be demonstrated by the FDA (Food and Drug Administration) 510(k) pre-market clearance review process whereby a new product gains approval by demonstrating substantial equivalency to one or more “predicate devices” on the market. Confirmation technologies, especially GC/MS, are used as the gold reference for immunoassay studies for 510(k) submission and are occasionally used as the predicate methods. Although increasing numbers of test-strip products have obtained clearance utilizing similar test-strip products as predicate devices, the first phases of on-site products were comparatively evaluated with instrumented, laboratory-based immunoassays to attain FDA approval.

11.5.2.1 Instrumented Immunoassays

The early concept of the “two-stage field testing procedure” involved the on-site collection of samples that could be preserved and transported in a convenient way for completing the instrumented testing in a laboratory. For “field” application, the samples can be absorbed onto paper disks such as a paper loaded with cation-exchange resin, dried, and mailed to the laboratory for radioimmunoassay (RIA).³⁰ The locally collected, sample-treated paper with ion-exchange resin could also be tested with hemagglutination-inhibition and spectrophotofluorimetry.³¹ In a 1976 review article, Cleeland et al.³² reported that the RIAs appear to be equally applicable to detection of drugs in urine, blood, saliva, and tissues, and “can be used equally well for emergency (STAT) tests or mass screening.”

Nonetheless, the most commonly utilized urine drug testing methodology for on-site facilities has been homogeneous immunoassays that can be easily performed using small automated analyzers. Reagents based on the principles of EMIT (enzyme multiplied immunoassay technique), and to a lesser degree, FPIA (fluorescent polarization immunoassay), and KIMS (kinetic interaction of

particles in solution), have all been utilized in the context of on-site laboratory testing. Examples of bench-top analyzers or newer analyzer families that offer models suitable for small- to medium-size laboratories include Dade Behring (Deerfield, IL) ETS-Plus, Viva, 30Rand V-Twin; Abbott (Abbott Park, IL) TDx, TDxFLx; Olympus (Melville, NY) AU series, and Roche (Indianapolis, IN) Hitachi Systems, Cobas MIRA-Plus, and Cobas Integra systems.

11.5.2.2 Non-Instrumented Drug Testing Products

Microparticle-Based On-Site Immunoassays

The utilization of hemagglutination-inhibition methods to detect abused drugs was reported in 1971.³³ Early versions of a non-instrumented testing device for abused drugs included a latex agglutination-inhibition-based testing device (Abutex) made available for investigation by Hoffmann-La Roche in the 1970s. By 1981, several Roche Agglutex products for abused drug screening had received FDA 510(k) approval. The Agglutex assays were available from the mid-1970s until the early 1990s; the method was reported to be easy to use and could accommodate analysis of “approximately a hundred specimens per hour without sophisticated instrumentation” although the results were available after a 2-h incubation period.³⁴ By contrast, the next generation of latex agglutination-inhibition based products, Roche Abuscreen OnTrak,^{35–44} produced results in approximately 4 min. The first wave of OnTrak products received FDA approval in 1988. A multianalyte agglutination assay was reported in 1993 by Abbott researchers⁴⁵ as a 10-min assay system for five classes of abused drugs.

Slide or capillary-flow microparticle-based POCT immunoassay products have the advantage of better-controlled reaction kinetics (liquid-phase, thorough reagent mixing, and incubation) and relatively easy visual interpretation of a positive or negative result. However, these assays are less versatile due to the requirements of liquid reagent storage and handling and were gradually replaced by membrane-based products in the past few years.

Membrane-Based Assays for Urine Drug Testing — One-Step Lateral Flow Immunochromatography

Paper strip-based immunochromatographic assays or “dipstick” assays have been explored for drug immunoassay development. The first application of lateral flow paper strip was disclosed in a 1978 patent that utilized immunochromatography to carry out an RIA.⁴⁶ In 1983, Litman et al.⁴⁷ reported “an internally referenced test strip immunoassay for morphine.” Enzyme-channeling immunoassay that involved sequential incubation of the strip in the sample and developer solution could “score the test as positive or negative for drug” based on the ratio of the color formed on the indicator pad to that formed on the reference pad. An enzyme immunochromatography based on “the spatial distribution of enzyme label” for analyte quantification⁴⁸ was used in the Syva Accu-Level product for therapeutic drug monitoring.^{49,50}

Earlier evaluations of paper chromatography tests for drugs of abuse screening in urine, such as the 1980 Technology Resources, Inc., TRI dipstick and the 1987 Keystone Diagnostic Inc. Quik Test, all indicated that the tests were inaccurate, unreliable, and unacceptable.^{51–54} By the mid-1990s, approximately a dozen membrane-based on-site products for screening drugs of abuse in urine were launched either by established companies in the drug testing business or by new companies founded to enter POC or drug testing markets. Examples of products marketed or evaluated during this time period include (in alphabetical order) Abusign (Princeton Biomeditech, Princeton, NJ),^{55,56} accu-PINCH (Hycor Biomedical Inc., Garden Grove, CA),⁵⁷ EZ-Screen (Environmental Diagnostics, Burlington, NC),^{58–61} Frontline (Boehringer Mannheim/Roche),^{62,63} microLine (DSSI, later Casco-Nerl, Portland, ME), OnTrak TesTcup and OnTrak TesTstik (Roche Diagnostics, now Varian, Inc., Irvine, CA),^{64–71} Rapid Drug Screening (American Bio Medica Corp. Kinderhook, NY), Triage

(BioSite, San Diego, CA),^{72–78} Verdict (Editek, Inc., now MedTox, Burlington, NC), Visualine (Sun Biomedical, Cherry Hill, NJ),⁷⁹ etc. Over time a number of POCT products or brands were either “on and off the market” — or completely changed product configurations.

From the late 1990s into the early 2000s, there has been a rapid proliferation in both the numbers and distributors of on-site drug testing products. Besides those in the U.S., the number of overseas manufacturers of POC drug testing products has also increased in recent years. Several of the on-site testing investigation projects either inventoried or evaluated the contemporaneous on-site testing products.^{20–23,28} The reports list descriptions of selected products and some of the different products that are in fact identical products. From published information and government databases, it can be noted that many products either share the same strip manufacturer or are essentially the same devices under different packaging or labeling. For products marketed under different trade names, their package inserts typically contain the same data because no additional studies are needed for FDA “Add-to-file” approval for selling the device with different trade names or labeling.

Collectively, divergent factors have contributed to the explosion of the number and types of POC drug testing products. Among the contributing factors are increased acceptance of on-site testing by the marketplaces, more recognition of the on-site testing benefits, more new companies and new alliances, and more “menu configurations” comprising various combinations of single and panel tests. Conversely, the lack of mandated or standardized regulations, the significant price erosion, and the promulgation of the Internet also contributed to blurring the entry barriers into the on-site drug testing markets.

Membrane-Based Drug Assays for Alternative Matrices

In addition to urine drug testing, some of the on-site testing products were evaluated for blood or post-mortem blood testing following blood extraction or acetone precipitation.^{80,81} However, the performance is different. In recent years, one-step lateral flow immunochromatography has also been the format of choice for most of the on-site drug testing for alternative matrices. Examples of on-site saliva testing products^{82–89} include (in alphabetical order) Drugwipe and DrugwipeII (Securetec, Ottobrunn, Germany), OralLab (Varian, Inc., Irvine, CA), OralScreen (Avitar, Inc., Canton, MA), RapiScan Cozart Bioscience Ltd. (Cozart Bioscience Ltd., U.K.), and SalivaScreen (Ulti-Med, Ahrensberg, Germany). The Drugwipe products are also marketed for drug detection in sweat or on the skin. These products are discussed in another chapter of this section. However, with more of the on-site urine test manufacturers expanding into the oral fluid testing field, the number of oral fluid testing products is likely to increase in the coming years.

11.5.2.3 Hybrid of Instrumented and Non-Instrumented On-Site Drug Testing

The “hybrid” system usually consists of a handheld “reader” to help interpret the color development result of an on-site testing strip. There are bench-top readers that can integrate sample-handling or testing procedures. Many of the test strip developers have developed readers for internal use or for products; moreover, a few generic strip readers are commercially available. Nevertheless, not all companies make the commercialization decision. Examples of on-site tests that have to be used in conjunction with an instrument include RapiScan (Cozart Biosciences), eScreen (eScreen, Inc., Overland Park, KS), etc. Currently, there are companies that can offer connectivity and multivendor information management for POCT. Some of the on-site device or service providers may offer customized data management for the needs of chain-of-custody and data entry, reporting, and storage.

The sensitivity of the reader depends on the quality of the optical components, resulting in a trade-off between the quality, the price, and the portability of the readers. Instruments that employ light reflectance or optical scanners may not achieve greater sensitivity than the human eye. Because the “gray zone” of color reading (weakly positive vs. weakly negative) also falls on the analytical gray zone of the testing result (around cutoff region of the calibration curve), the overall interpre-

tation accuracy is not significantly affected by human or machine reading. However, the human subjectivity and lighting issues can both be minimized by instrument reading. The instrument reading also offers benefits in result recording and processing, although it carries additional cost and handling and quality control of the readers. Therefore, the choice of adopting the hybrid system is at the discretion of the users for their drug testing program budget and goals.

Specific readers are required for assays that utilize fluorescence or phosphor particles to achieve lower detection limits for certain analytes, especially for oral fluid drug testing. The Uplink analyzer developed by OraSure Technologies, Inc. (OTI) is a portable instrument containing a laser source that “interrogates” the test strip based on Up-Converting Phosphor Technology (UPT).⁹⁰

A few research reports have shown the feasibility of applying immunosensor technology to drug testing.^{91,92} The future development of immunosensor-based on-site drug testing may potentially be applied to “smart” handheld devices with more digital capability in result processing, wireless transmission, and data management.

11.5.3 Principles of Detection Reactions

The majority of on-site drug testing products utilize microparticles to maximize reagent reaction surfaces and to allow detection of the outcome of the competitive immunoassays. Microparticle agglutination-inhibition assays such as Abuscreen OnTrak assays use relatively large white microparticles with coated drug-conjugate to bind antibody and produce visible latex aggregates in the absence of drugs. The presence of drugs above the designated cutoff level prevents the agglutination and produces a milky appearance, indicating a screening positive result. Membrane-based assays utilize smaller colored nanoparticles with attached antibody to bind pre-immobilized drug conjugate and produce a color signal. The binding can be inhibited by drugs in the sample so the absence of the color signal indicates a screening positive result.

Membranes such as nitrocellulose or nylon membrane have become the key component of POC immunoassays. In rapid POC immunoassays, membranes not only provide means for separation of the bound and unbound but also serve as solid-phase reaction chambers. There are two major forms of membrane-based tests: lateral-flow and flow-through. Lateral flow is the most commonly used “one-step assay” because of its ease of use. The “convective mass transfer” of the immunoreactant to the binding partner allows the assay to be performed upon the initiation of sample flow. However, immunoreactions in a lateral flow strip are not carried out under an equilibrium condition, which results in certain degree of compromise in reaction kinetics when compared with assays performed in an equilibrium mode. Various chemical, reagent, and process optimizations, most of them proprietary, have been actively sought to enhance performance and manufacturing consistency while maintaining the one-step advantage. The plastic housing for lateral flow test strips is typically a self-contained device that has all the reagents necessary to complete a test.

The flow-through tests typically involve the handling of liquid solution and require more than one step of user intervention. Thus the flow-through form can require more manual manipulation and need more time to carry out tests for the same groups of analytes; however, the trade-off allows incubation of immunoreaction components in liquid state until they reach a predetermined near-equilibrium state. The system with sequential incubations and washing may help to reduce residual nonspecific binding and can be more forgiving of potential sample matrix effects. The assembly of flow-through assays usually is a single device designed to allow for wicking of the sample and excess reagents.

11.5.3.1 One-Step Lateral Flow Immunochromatography

Typically, the basic test configuration comprises a nitrocellulose membrane strip with an immobilized capture reagent, which contains one member of the antigen–antibody binding pairs. The detection reagent consists of colored nanoparticles, which have been sensitized with the comple-

mentary binding partner. The strip also contains other components to modulate optimal immunoreactions. For drugs of abuse testing, the immobilized reagent is usually a drug derivative that has been covalently attached to a large molecular carrier protein (i.e., drug conjugate). There are two types of nanoparticles used in the reaction of visual-read lateral flow assays: metal sol (usually colloidal gold) or colored latex nanoparticles. The particle size and uniformity of colloidal gold require optimal manufacturing control with an ideal diameter of gold particles for lateral flow assays of around 40 nm. In contrast, the choice of colored uniform latex particles is typically in the 100- to 300-nm range.

The constructions of lateral flow strips have previously been described in detail, as the examples include a representative colloidal gold-based test strip configuration⁹³ and a blue latex-enhanced immunochromatography.⁹⁴ In brief, lateral flow immunoassays are based on competition between the drug, which may be present in the sample being tested, and the immobilized drug conjugate for binding to specific antibodies on the surface of the nanoparticles. If drug is present in the sample being tested, it binds with the antibody and inhibits the antibody reaction with the drug conjugate. Subsequently, no color is observed in the test results area. If the sample being tested contains drug below the cutoff concentration or is drug-free, the antibody is free to bind with the drug conjugate and a color band develops in the test results area. A second line, a control, may also be formed on the membrane by excess nanoparticles, indicating the test is complete or valid.

Lateral flow strips can be designed to test for one or more analytes in a single strip or for panel testing in a single housing containing several strips. For drugs of abuse assays, the test can be completed within 3 to 5 min of sample application. The results of colloidal gold-based strips need to be interpreted within a few minutes of assay completion (most package inserts specify the results reading time limits). The results of blue latex-based strips can stay stable for longer periods of time and the results can be read upon tester convenience for up to a few hours after assay completion.

Lateral flow assays have also been applied to use with up-converting phosphor reporters and the UPLink reader for detecting drugs in oral fluid.⁹⁰ UPT nanoparticles are lanthanide-containing ceramic particles that can absorb infrared light and emit visible light. The UPLink reader contains a miniaturized infrared laser and can measure the signal intensity of the lines for conversion to qualitative results.

11.5.3.2 Multistep, Liquid Reagent, and Membrane-Based Assays

One example of a membrane-based enzyme immunoassay is EZ-SCREEN.⁶¹ The testing card contains antibody immobilized in the reactive area. Testing sample, along with positive and negative controls, is added to the reactive area as indicated on the card. Then the enzyme conjugate solution, wash reagent, and substrate reagents are added sequentially. The presence of drug in the testing sample competes with the drug–enzyme conjugate for binding to the membrane-embedded antibody and thereby reduces the color development after the substrate is added. The results are interpreted in 3 min by comparing color in the sample reaction site to that of the positive control site. The color differentiation of positive and negative control sites serves to indicate if the test is valid or not.

Another example is ASCEND MultiImmunoAssay (AMIA) that employs two reaction phases and a wash step for Triage drug panel testing.^{72,78} The first step involves the incubation of a pre-defined sample volume in a reaction well that contains three lyophilized reagent beads. After 10 min, the reaction mixture is transferred to a membrane solid phase with immobilized antibodies in discrete drug detection lines. The results can be interpreted visually after allowing the complete soaking of the reaction mixture and a subsequent wash of the membrane. The three reagent beads contain the set of antibodies for the analytes of interest, the corresponding drug derivative-colloidal gold conjugates, and reaction buffer, respectively. The drug conjugate competes with the corresponding drug in the donor urine for limited antibody binding sites. Competition of drug conjugate and drug in the urine for antibody binding occurs in the solution phase. When the reaction mixture is transferred to the testing area, freed drug conjugate can bind to its respective antibody on the

test-plate membrane. After washing, positive result produces a reddish-colored bar in the drug detection zone adjacent to the drug name whereas negative sample produces no color. The results are read within 5 min of completion.

11.5.4 General Operational Considerations

11.5.4.1 Testing Flow and Confirmation

In general, workplace programs that use POCT are more likely to follow the same chain-of-custody and testing flow as laboratory-based drug testing programs. Depending on the industrial sectors, company size, and local and state regulations, however, the actual practice of workplace testing can vary dramatically. In contrast to workplace testing, NACB discourages the maintenance of chain-of-custody documentation for clinical toxicological purposes²⁴ unless it is known in advance that a specimen will likely be involved in a medicolegal matter. For compliance testing programs, the practice can range from those following regulated testing flow to those conducting tests in front of the person being tested.

All the drug testing immunoassays are required by the FDA to clearly emphasize on product labeling that screen results are only preliminary and a more specific alternative chemical method must be used to obtain a confirmed analytical result. For the diverse end users of on-site drug immunoassays, however, the decision to confirm is at user discretion. The two-tier screening and confirmation system has not yet been a “mandate” for non-federal-regulated testing programs; however, many of the workplace testing programs do establish the confirmation requirements. Testing programs that employ full-service providers can have service bundled from collection to confirmation and reporting. For clinical testing, however, NACB considers the need for obtaining STAT results as negating the value of confirmation in emergency cases and recommends against routinely performing confirmative analyses on positive screening results.²⁴ If the clinician anticipates subsequent involvement with medicolegal or social services or clinical need to identify a specific drug, the staff should notify the laboratory for a confirmation analysis.²⁴ In criminal justice and drug treatment programs, user admission of drug use following a positive on-site screening result may be sufficient to waive further confirmation. However, in many cases confirmation is required for legal reasons and specific regulations.

11.5.4.2 Training

Similar to other aspects of on-site drug testing, training for using the products and interpreting the results can vary from program to program. The most popular mode of training is for the manufacturers/device providers to develop the training materials, audio-visual aids, and documentations. The manufacturers provide the first tier of training directly or through a third-party organization. The customers may have the option to set up a “training the trainers” program. The training typically involves presentations and reading materials, live demonstrations, and hands-on training using known controls and blind samples. Written examinations and certificates are mechanisms to certify the completion of training. The manufacturers can also develop interactive web-based e-learning training. With the wide spectrum of device providers, however, the quality, delivery, and outcome of the training may vary considerably.

11.5.4.3 Quality Control and Quality Assurance

Unlike the instrumented laboratory-based immunoassays that employ on-board calibrations and controls, single-use POC test strips are precalibrated during the manufacturing process. Manufacturers that follow good manufacturing practices with validated procedures typically specify multiple

steps of batch- and lot-based quality controls at both the test strip production phase and the finished-goods stage.

In theory, the majority of on-site drug testing devices have built-in procedural controls that should not be confused with analytical controls. One-step, competitive lateral flow assays contain one antigen–antibody pair of reagents and employ one control line downstream from the result zone. Multistep assays such as AMIA require two control lines to ensure that the test procedure is valid. In reality, these built-in controls do not verify the actual immunoreactions of the devices to target drug(s) and the only method of true “control” is via the use of externally prepared and validated drug-containing and drug-negative controls. The built-in test valid zones can be designed to visually correspond to the positive and negative results; however, the quality control recommendation in all device package inserts includes running external controls.

Quality assurance (QA) is a comprehensive program that provides constant surveillance of all aspects of a laboratory or a testing facility. Quality control is an important part of a QA program and is used to ensure the accuracy of the tests. The implementation of a QA program and the use of quality control for POC drug testing are both client-driven. Although Clinical Laboratory Improvement Amendments (CLIA) exempt drug testing, many clinical testing and some state workplace testing regulations have requirements that are equivalent to or stricter than CLIA. Most of the clinical testing and some of the testing programs require daily run of external positive and negative controls unless special exemption is granted. In nonclinical testing, the more typical practice is to run quality controls either at fixed time intervals or when starting to use a new shipment or new lot of devices. A number of testing programs and devices also participate in open and blind proficiency testing.

11.5.5 Product Comparison Studies

A number of studies have evaluated and compared the performance of rapid POC drug tests. Reports investigating the performance of POCT devices generally fall into five categories:

1. Detailed description and performance summary of one particular or two similar device types^{34–40,43,49–54,51–80,82–88,95,96}
2. General comparative evaluation of a number of different on-site devices and/or laboratory-based immunoassays^{28,41,42,44,55,81,89,97–101}
3. Comparative challenges of the devices with samples specifically selected to test the limits of immunoassay screens, such as near-cutoff performance or challenge of potential cross-reactivity issues^{20,21,103,104}
4. General comments or reviews^{3,5,9,10,27,105,106}
5. Field studies^{7,8,22,23,29,102}

When comparing results from these studies, it is always crucial to recognize that different study goals, sample selections, and protocols can dramatically influence the outcome and interpretation of these studies. It is also important to take into consideration the target analyte and cutoff selections of the assays as well as the type and prevalence of the testing population. There are voluminous references but only examples of cutoff-challenge studies or field studies are briefly reviewed in this chapter.

11.5.5.1 Studies That Emphasized Near-Cutoff Challenges

In 1999, SAMHSA published a Division of Workplace Programs-sponsored evaluation of on-site testing that was designed to challenge 15 non-instrumented devices and an instrument-immunoassay on their accuracy near the cutoff.²⁰ The DWP-sponsored evaluation and its predecessor,

a study carried out for the Administrative Office of the U.S. Courts, were subsequently published as a book chapter.²¹ Although there are trade-offs of sensitivity vs. specificity when the majority of the samples evaluated are within $\pm 25\%$ of the cutoff values, the report stated that performance of most on-site devices was comparable to that of an instrument-based immunoassay. The overall accuracy of all drug test results vs. GC/MS (HHS cutoffs) ranged from 63% (PharmScreen DS) to 78% (OnTrak TesTstik), as compared to the accuracy of 76% for instrumented EMIT assays. The authors commented that the “favorable performance” of these devices was “encouraging.” Moreover, “it is expected that specimens encountered in most workplace testing situations will have fewer specimens with drug concentrations near the cutoff.”²⁰ Therefore, “a much higher percentage of confirmed positive results and fewer false negative results should occur during actual testing in the field.”

With the similar principle of “using challenging clinical sample sets” containing drug concentrations close to the screening cutoffs, Kadehjian¹⁰⁴ compared the performance of five on-site drugs-of-abuse testing devices (microLine, TesTcup5, RapidTest, RapidCup, and Triage) and an instrumented test (Emit d.a.u.). In this study, 298 specimens were tested on each of five devices and each result was independently read by two operators. There was little difference in overall accuracy between the scientist and nonscientist readers. The percent borderline results ranged from 10% (RapidCup) to 32% (microLine), whereas the accuracy of borderline results ranged from 34% (Triage) to 82% (TesTcup). More importantly, the author reported that accuracy generally improved with all devices demonstrating predictive values between 0.98 and 1.0 when device performance was assessed according to drug presence/absence criteria.

11.5.5.2 Field Evaluations

In 2000, the U.S. DOT published a study sponsored by the National Highway Safety Administration (NHTSA), “Field Test of On-Site Drug Testing Devices.”^{22,23} In this study, 30 on-site products were identified and 16 devices were rated based on 14 criteria. From the rating results, five devices (AccuSign, TesTcup5, TesTstik, Rapid Drug Screen, and Triage) were selected to evaluate 800 samples in two high drug prevalence counties in New York and Texas. The study had police officers participate in the actual use of the devices. Samples that showed positive results for any assay from any of the devices and 5% of the samples that showed negative results on all devices were sent to a laboratory for confirmation. The unconfirmed positive rates as a percentage of all samples tested (drug present in concentrations below the MS confirmation cutoff) were as follows: 0.12% for amphetamines, 1.0 to 1.12% for cannabinoids, 0.5 to 1.37% for cocaine metabolites, 0.25 to 0.37% for opiates and PCP, respectively. The false negative rates were as follows: 0% for amphetamines, 0.25 to 0.87% for cannabinoids, 0.12 to 0.37% for cocaine metabolites, 0 to 0.12% for opiates, and 0 to 0.25% for PCP. The report indicated that, when cutoff concentration and additional drugs are taken into consideration, the POCT devices were accurate in identifying positive samples and rarely failed to identify a driver with the target drugs in urine. Participating police officers generally favored the use of on-site devices in the enforcement of impaired driving laws. Nonetheless, the use of these devices should not supplant the officer’s judgment regarding impairment.

Another field evaluation of on-site, multi-analyte drug testing devices as tools to identify drivers under the influence of drugs was funded by HHS/NIDS and reported by Buchan et al.⁸ During the 4-month study in a Florida county, voluntary and legal urine specimens were collected from suspects placed under arrest for suspicion of DUI and 303 samples contained a sufficient volume of urine for testing and confirmation. Specimens were tested in a university laboratory using four different POCT kits (AbuSign, TesTcup, Abuscreen OnTrak, and Triage). Results indicated that the accuracy ranged from 97.4 to 98.0% for THC, 97.4 to 98.0% for cocaine, and 99.7 to 100% for opiates. The authors observed that the four kits were in very close agreement on prevalence (15.5 to 15.8% for THC, all at 13.2% for cocaine, and all at 0.7% for opiates).

11.5.6 Examples of POC Drug Testing Applications

11.5.6.1 Testing in the Workplace

Technical standards established for federally mandated workplace testing have withstood a number of constitutional challenges and served as a model for some state statutes for Drug-Free Workplace and for voluntary employer drug testing programs. Ideally, POC workplace drug testing by and large should follow this model. The portable and qualitative nature of on-site drug testing devices, however, can be a serious challenge to the “safeguards” that were built into the mandated program. In private sector workplace testing, employers may use their discretion on how to conduct POC testing or to contract to third-party or comprehensive drug testing service providers. Regardless of where and how a test is performed, a reliable workplace testing program has to take into consideration specimen collection (site, personnel, device, and procedure), donor and specimen (integrity, security, privacy, chain-of-custody, storage or transfer), result (handling and reporting), quality (QC, QA), and outcome management (confirmation, medical review officer).

The most prominent example of large-scale application of on-site drug testing in the workplace has been the U.S. Postal Service (USPS) drug testing program.¹⁶ USPS started a pilot program in 1997. The pilot study involved a variety of different validation studies using both clinical and spiked specimens that involved four collection sites and large numbers of side-by-side studies over several months. In 1999, USPS decided to make the pilot project a full-time program. USPS has now implemented POCT in more than 1000 collection sites nationwide. The USPS example demonstrates that a well-planned and well-structured on-site workplace drug testing program can be effective and sustainable even when it involves a large number of geographically diverse sites.

11.5.6.2 Testing in Clinical Settings

Controversies continue to exist regarding the value of urine drug testing in clinical settings. The cited reasons for the controversies include the drugs involved, the sample, the methods utilized to perform the tests, and the level of understanding of the physician using the data.¹⁰⁷ Despite the demand for rapid results in emergency situations, the immunoassays “are often designed for, or adapted from, workplace testing and are not necessarily optimized for clinical applications.” The study authors concluded that “While the literature is replete with studies concerning new methods and a few regarding physician understanding, there are none that we could find that thoroughly, objectively, and fully addressed the issues of utility and cost-effectiveness.”¹⁰⁷ Likewise, NACB considers that immunoassays, although rapid, have major limitations in sensitivity and specificity.²⁴

Even so, the features of fast TAT and panel screening have helped POC drug testing to become a viable technology in clinical settings. In comparison to the SAMHSA-5 panel for workplace testing, on-site testing devices for the clinical settings contain additional assays for benzodiazepines, barbiturates, and/or tricyclic antidepressants. Although assays for cannabinoids and phencyclidine are considered not useful in general clinical testing, on-site products for the clinical market generally contain a menu of eight to ten assays. Examples of products evaluated for on-site clinical testing include the market leader Triage DOA panel as well as ABMC Rapid Drug Screen, Dade Behring RapidTest, Abbott Signify-ER, Roche TesTcard 9, TesTcup-ER, BioRad Tox-See, etc.^{28,38–40,69,72–78,95–96} According to the Biosite promotional material, on-site drug testing has been used in over 2500 U.S. hospitals, indicating that on-site devices also can be effective and sustainable in the clinical market.

11.5.6.3 Testing in the Criminal Justice Systems

The utility of urine drug testing as an objective and effective tool to identify and treat substance abusers within the criminal justice systems has been well-recognized and is fully documented in

another chapter of this section.⁹ The major market segments for drug testing within the criminal justice systems include community corrections, institutions and prisons, rehabilitation, and law enforcement. Community corrections, such as probation and parole, security, pre-trial services, and drug courts, are among the largest of the four segments to adopt non-instrumented devices for POC drug testing.

Road-side drug testing and DUI programs can be categorized in the law enforcement segment. These applications have been thoroughly evaluated in studies sponsored by government or organizations such as DOT, HHS/NIDS, and ROSITA.^{8,22,23,29,102}

11.5.6.4 Other Applications — Testing at School, Home, and Direct Consumer Testing

Examples of more recent uses of POCT include school and home testing. These applications are still evolving and will not be discussed at this time. Regardless of the sources of on-site testing devices (e.g., over-the-counter retailers, pharmacy, or Internet), the direct consumer sales of both on-site drug testing device and drug testing adulterants signal an intriguing era of drug testing. Together with the drug and drug testing “knowledge” from Internet and multimedia information sources, people have the means to test themselves before reporting to a drug test or to titer or experiment with the use of both drugs and adulterants. There are a number of ethical questions regarding lay misuse of the devices and non-consent testing but the topics are beyond the scope of this chapter. Recently, the U.S. FDA established a specific Web site for home drug tests;¹⁰⁸ this is a resourceful online tool that provides clear yet comprehensive explanations of the two-step drugs of abuse tests.

11.5.7 Continuing Evolution and Future Trends

The evolution of on-site drug testing has truly come a long way. Since the 1980s, the challenges of exploring the “new” POCT markets have included the diverse marketing requirements, different laws and individual state legislation constraints, lack of permission in regulated testing, legal and interpretation considerations, and various market acceptance criteria and customer expectations. To date, some of the challenges remain critical but the tests continue to be popular for several reasons. The simple operation to produce visible results within a few minutes has been an attractive feature. Most importantly, the major products have had proven performance for customer needs that not only established customer and legislative acceptance but increased the practical utility of POCT as part of the drug testing programs. In general, these rapid assays can provide comparable performance with conventional immunoassays in most drug-screening settings. The near-cutoff precision is typically better with laboratory instrumented assays; however, on-site assays are useful for routine drug screening in the markets that demand rapid, qualitative determination. The trend of adopting POC drug testing appears to continue into the foreseeable future even though the market growth has been leveling off.

Considering the dynamics of the diagnostic industry and drug testing business, the description of POCT product development in this chapter is not an attempt to be all-inclusive. Companies often make business decisions concerning alliances, divestiture, and acquisition to best meet their strategic considerations and goals. Naturally the business activities will continue into the future and can influence not only existing products but also future development of on-site drug testing. In addition, the World Wide Web and globalization will continue to influence on-site drug testing. Besides regular e-commerce activities of product providers, there are plenty of independent Web sites selling assortments of trade-name and generic on-site drug testing devices on the Internet. Additionally, many drug testing “full service providers” and “re-sellers” (third-party administrators, labs, distributors, medical review officers) have bundled into their service on-site drug testing devices from a variety of device manufacturers. Ironically, the Internet era also considerably boosts the adulter-

ation industry, and most of the Web sites that sell drug testing adulterants also sell on-site drug testing devices for self-titration of drug use and for user self-testing.

Because drug testing can have decisive medicolegal and social consequences, the industry is closely affected by regulatory and legislative issues and decisions. In general, most of the companies that are active in the on-site drug testing business are members of major industrial associations such as NOTA (National On-Site Testing Association) and DATIA (Drug and Alcohol Testing Industry Association). NOTA is an advocacy and resource center for on-site drug and alcohol testing. DATIA was founded in 1995 as the National Association of Collection Sites, and has since expanded its scope to represent the entire spectrum of drug and alcohol service providers, including collection sites, laboratories, consortiums/third party administrators, medical review officers, and testing equipment manufacturers. The two associations have worked independently or collaborated on behalf of on-site drug testing and will continue to play important roles in the future of on-site drug testing.

The limitations of immunoassay for drug screening apply to both laboratory-based instrumented testing and on-site testing. Because the understanding of antibody cross-reactivity issues and various cutoff decisions requires knowledge of immunoassay and drug testing, interpreting and reporting results can continue to be issues with on-site drug screening unless safeguard requirements are built into the testing program. There is more to a drug testing program than just results and the success of an on-site testing program relates to how it is structured and implemented. The draft for the next versions of SAMHSA federal guidelines takes into considerations many of these requirements for conducting POCT.⁴ Meanwhile, the FDA is revising its guidance of pre-market submission for drugs of abuse screening tests by combining the previous drafts for prescription and over-the-counter drug screening into one draft.¹⁰⁹ These new regulatory developments both recognize the co-existence of conventional laboratory tests and on-site screening for drugs of abuse. All of these developments will continue to shape the future of on-site drug testing.

CHAPTER 12

Post-Mortem Toxicology

Edited by Henrik Druid, M.D., Ph.D.

Associate Professor, Department of Forensic Medicine, Karolinska Institute, Stockholm, Sweden

CONTENTS

12.1	Introduction to Post-Mortem Toxicology	965
12.1.1	Medicolegal Death Investigation	965
12.1.1.1	The Role of Police and Medical Examiner Investigators	965
12.1.1.2	Role of the Forensic Pathologist.....	967
12.1.2	Certification of Death.....	967
12.1.3	The Role of Toxicology in Death Investigation.....	968
12.1.3.1	Homicides.....	969
12.1.3.2	Suicides.....	969
12.1.3.3	Accidents	969
12.1.3.4	Natural Deaths.....	970
12.1.3.5	Unclassified, Undetermined, or Pending	970
12.1.3.6	Pending Toxicology (Overdose).....	970
12.1.4	The Toxicology Examination.....	971
12.1.4.1	Poisons.....	971
12.1.4.2	Comprehensive Toxicology Screening.....	971
12.1.4.3	Case Review	972
12.1.4.4	Quality Assurance	972
12.1.4.5	The Toxicology Report	972
12.1.4.6	Toxicological Interpretation	973
	References	973
12.2	Specimen Selection, Collection, Preservation, and Security.....	975
12.2.1	Chain of Custody	976
12.2.2	Specimen Collection	976
12.2.2.1	Specimen Containers.....	976
12.2.2.2	Specimen Preservatives	977
12.2.3	Sampling.....	977
12.2.3.1	Blood	978
12.2.3.2	Urine	979
12.2.3.3	Bile	979
12.2.3.4	Vitreous Humor	979

12.2.3.5	Gastric Contents	979
12.2.3.6	Hair	980
12.2.3.7	Tissues	980
12.2.3.8	Labeling	980
12.2.4	Selection of Post-Mortem Specimens	981
12.2.4.1	Blood	981
12.2.4.2	Urine	982
12.2.4.3	Bile	982
12.2.4.4	Vitreous Humor	983
12.2.4.5	Gastric Contents	983
12.2.4.6	Tissues	984
12.2.4.7	Hair	984
12.2.4.8	Bone and Bone Marrow	985
12.2.4.9	Skeletal Muscle	985
12.2.4.10	Larvae	986
12.2.4.11	Meconium	986
12.2.4.12	Other Specimens	987
12.2.5	Nonbiological Evidence	987
	References	988
12.3	Common Methods in Post-Mortem Toxicology	991
12.3.1	Analytical Chemistry in Post-Mortem Toxicology	991
12.3.2	Simple Chemical Tests	992
12.3.2.1	Useful Color Tests	993

Due to the continuous increase in availability and use of pharmaceuticals and illicit drugs, post-mortem toxicology has become more and more important in death investigations. The introduction of new substances on the market requires a high awareness among pathologists and toxicologists and necessitates the development of methods that encompasses the newcomers. Fortunately, many important achievements have been made in methodology, and the application of novel techniques, such as modifications of solid phase extraction and LC/MS techniques, now offers better conditions for efficient and sensitive analyses of numerous substances.

Many important contributions regarding the impact of various post-mortem changes that may influence the toxicological results have been published. Pharmacogenetic analyses, e.g., to identify poor metabolizers, may now be applied on post-mortem material and assist in the determination of the manner of death, and studies on post-mortem redistribution of drugs have resulted in a widespread appreciation of the influence of the specimen type on the drug concentrations.

In recent years, the specific detection of many compounds and their metabolites in various matrices has improved substantially. However, the interpretation of their concentrations remains a difficult task. Hence, despite the progress in post-mortem toxicology, information about previous drug use and the circumstances surrounding death, and the autopsy findings are still very important

in order to arrive at correct conclusions when interpreting the analytical results. An intimate collaboration between toxicologists and pathologists is therefore desirable.

12.1 INTRODUCTION TO POST-MORTEM TOXICOLOGY

W. Lee Hearn, Ph.D.¹ and H. Chip Walls, B.S.²

¹ Director, Dade County Medical Examiner Toxicology Laboratory, Miami, Florida

² Department of Pathology, Forensic Toxicology Laboratory, University of Miami, Miami, Florida

12.1.1 Medicolegal Death Investigation

The medical examiner's office investigates sudden, violent, unnatural, or unexpected deaths,¹⁻³ and the medical examiner, coroner, or pathologist is responsible for determining the cause and manner of death. The cause of death is the injury, intoxication, or disease that initiates a process leading to death, and if that initial event had not occurred, the individual would not have died. Death may follow years after the causal event. The manner of death is the circumstances in which the cause of death occurred. Five classifications are used to categorize the manner of death: homicide, suicide, accident, natural, and undetermined. Anatomic findings elicited at autopsy are often insufficient to determine the manner of death.

To determine the manner of death, all available information pertaining to a particular case, including the terminal events, scene investigation, police reports, social and medical history, autopsy findings, and results of histologic and toxicologic testing, must be considered. The question "Did alcohol, other drugs, or poisons cause or contribute to this person's death?" must always be answered. Success in arriving at the correct conclusion depends on the combined efforts of the pathologist, the investigators, and the toxicologist. The process of death investigation and the role of the laboratory are outlined in Figure 12.1.1.

12.1.1.1 *The Role of Police and Medical Examiner Investigators*

When a death is reported to the medical examiner's office, a case investigator will obtain certain information to determine whether the case falls under the jurisdiction of the medical examiner. The following is a list of important topics to consider, which may vary according to jurisdiction:

Cases Requiring Medicolegal Death Investigation

1. Any death where any form of violence, whether criminal, suicidal, or accidental, was directly responsible or contributory.
2. Any death caused by an unlawful act or criminal neglect.
3. Any death occurring in a suspicious, unusual, or unexplained fashion.
4. Any death where there is no attending physician.
5. Any death of a person confined to a public institution.
6. The death of any prisoner even though both the cause and manner appear to be natural.
7. Any death caused by or contributed to by drugs or other chemical poisoning or overdose.
8. Any sudden death of a person in apparent good health.
9. Any death occurring during diagnostic or therapeutic procedures.
10. Any fetal stillbirth in the absence of a physician.
11. Any death where there is insufficient medical information to explain the individual's demise.

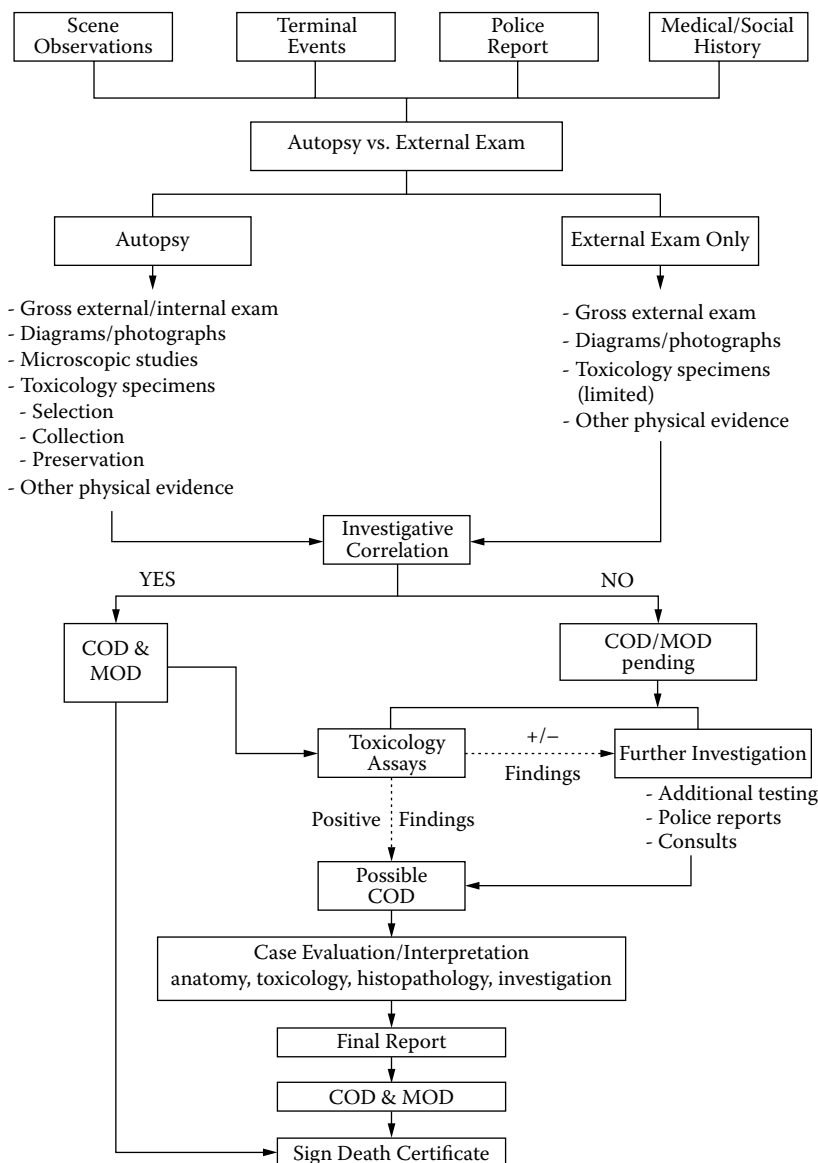

Figure 12.1.1 Overview of death investigation.

An unnatural death is any death that is not a direct result of a natural, medically recognized disease process. Any death where an outside, intervening influence, either directly or indirectly, is contributory to the individual's demise, or accelerates and exacerbates an underlying disease process to such a degree as to cause death, would also fall into the category of unnatural death.

Investigators are the eyes and ears of the medical examiner, especially in cases where the body is removed prior to the pathologist's involvement. The importance of an adequate investigation into past social and medical history cannot be overemphasized.

Police reports and investigations provide scene documentation. Typically, a report will include a description and identification of the body, time and place of death, eyewitness accounts, drugs present, and photographs. Investigators assigned by the medical examiner collect all items and information pertaining to establishing the cause and manner of death. Investigators contact the

family and friends of the deceased for information regarding, for example, past medical and social history and prescribed medications. Many cases have histories of prescription drugs to guide the investigation. All medication bottles should be verified as to content and count, in addition to performing a routine pharmacy check of the person's medication usage. Medical examiner investigators must also contact hospitals and treating physicians to obtain copies of medical records and police agencies to obtain arrest records. Progressively, a file is assembled that contains all of the relevant background information to assist the pathologist in understanding the medical and social history of the deceased.

The medicolegal systems in countries outside the U.S. vary, but the selection of cases subjected to a forensic pathology examination is usually similar. However, in several countries the police are responsible for the investigation even in noncriminal cases. It is therefore important that the pathologists and toxicologists stay in good contact with the investigating police officer to obtain all relevant information outlined above.

12.1.1.2 Role of the Forensic Pathologist

The principal role of the forensic pathologist is to investigate sudden, unexpected, and violent deaths in order to determine the cause and manner of death. In suspected drug-related deaths or poisonings, the pathologist must both exclude traumatic or pathological mechanisms as possible causes of death *and* select and preserve appropriate specimens for toxicologic analysis. After autopsy, cases can often be divided into two categories: those with an anatomical cause of death and those without. Few drugs leave telltale signs so obvious that the pathologist can determine a manner and cause of death without additional testing. Obvious exceptions include liver necrosis caused by acetaminophen, or the severely hemorrhagic gastric mucosa and smell from cyanide exposure, or coronary artery disease and cardiac enlargement in a cocaine user. Negative findings require toxicological analyses.

Approximately 10% of the cases submitted for toxicology do not have any guiding features. However, many of the thousands of potential compounds that could have caused death will have already been eliminated after history and autopsy results are correlated. Since the majority of drugs and poisons do not produce characteristic pathological lesions, their presence in the body can be demonstrated only by chemical methods.

Collection and preservation of appropriate specimens is a critical component of the autopsy examination.⁴⁻⁹ Just what is collected depends, at least partly, on the policy and finances of the department. The utility of these specimens depends not only on the condition of the body, but also on the pathologist's technique. Specimens must be large enough, the correct preservative must be used, and they must be placed in appropriate, clearly and correctly labeled containers.

Specimen collection is the first link in the chain of custody. Sample integrity within the chain of custody is an essential requirement for the rest of the forensic investigation. In cases where autopsy fails to determine a cause of death, or where there is an incomplete investigation, it is imperative to collect an adequate variety of specimens. Subsequent findings may modify or narrow the field of search, and make it unnecessary to examine each specimen, but they can always be discarded. However, many toxins are completely lost in the embalming process, so if the appropriate specimens are not collected at the time of the initial post-mortem examination, the cause of death may never be determined.

12.1.2 Certification of Death

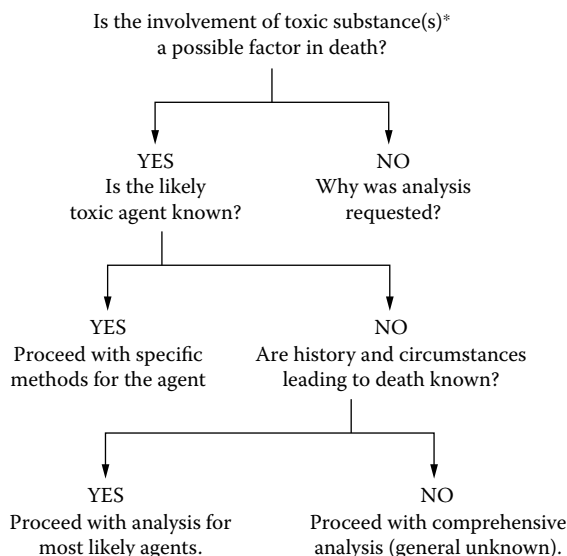

Each state requires a medical and legal document known as the Death Certificate be filed with the Bureau of Vital Statistics. The certificate contains demographic information as well the cause

and manner of death as determined by the medical examiner. Five different classifications are recognized: (1) homicide, (2) suicide, (3) accident, (4) natural, and (5) undetermined.

The results from toxicological analyses of post-mortem specimens are applied to determine whether drugs or toxins are a cause of death, or whether they may have been a contributing factor in the death. Negative toxicological results may be equally important as positive results, and sometimes even more meaningful as in the case of antiseizure medicines not detected in a suspected seizure death as compared to a positive marijuana test in the urine of a shooting victim.

12.1.3 The Role of Toxicology in Death Investigation

Most toxicology offices have established routines for specific types of cases, and the pathologist often provides some indication of what toxicological testing should be performed on each case (Figure 12.1.2). It would appear that cases of suspected homicide require much more thorough testing than obvious cases of accidental or natural death, but that is not really the case. Alcohol and other sedative hypnotic drugs, for example, are often detected in fire victims and may well have contributed to the cause of death.

***Forensic Questions Relative to Poisoning:**

1. Was the death or illness due to a poison?
2. What toxin produced the illness?
3. Was the substance employed capable of producing death?
4. Was a sufficient quantity taken to produce death or toxic results?
5. When and how was the toxin taken?
6. Could a poisoning have occurred and the poison either be or have become undetectable?
7. Could the detected poison have an origin other than in poisoning?
8. Was the poisoning SUICIDAL, ACCIDENTAL, OR HOMICIDAL?
9. Were the correct specimens collected and preserved, analyzed in such a manner to answer the question at hand?

Figure 12.1.2 Identification of a toxicology issue in the death investigation.

12.1.3.1 Homicides

The relationship between intoxication and violence is well recognized.^{10–12} Toxicological studies in cases of traumatic homicide should include tests for alcohol, prescribed medications, and other drugs. Negative findings can be used in court to rebut assertions of self-defense against a “drug-crazed” attacker. Positive findings may help explain how the victim became involved in a physical altercation. In addition, results of drug screening provide information about the deceased’s lifestyle that may prove useful to police as they search for the murderer. Toxicological investigations may also reveal evidence that a victim was drugged to incapacitation and then murdered.

12.1.3.2 Suicides

In cases of suicide, investigators try to discover an explanation for the act.^{13–15} People may be driven to suicide by failing health, financial problems, loss of a loved one, severe mental depression, or other causes. Drugs that can potentiate or exacerbate depression are commonly detected in suicides. A well-recognized drawback with antidepressants is that they neutralize passivity and inhibition before they affect the mood, and thereby confer an increased risk for suicide during the first weeks of treatment.^{16,17} Drugs commonly found in suicide victims include alcohol, sedatives (particularly benzodiazepines), analgesics, and hypnotics, and sometimes even illicit drugs. Therefore, toxicological investigations should encompass a large number of intoxicants. Occasionally, a suicide victim employs multiple means to reduce the chances of survival, implying that intake of drugs should not be overlooked even if another suicidal method is apparent.

12.1.3.3 Accidents

For fatal accidents, highway crashes immediately come to mind; however, accidental deaths occur in many other circumstances.^{9,11,18–22} Drownings, falls, fires, electrocutions, boating accidents, and aircraft crashes, as well as accidental drug overdoses, are included in this classification. Accidents often result from carelessness or the impairment of mental or motor function on the part of the victim or another person. In apparent cases of accidental death, it is important to confirm or rule out alcohol- or other drug-induced impairment. Many insurance policies exclude death or injury resulting from the misuse of intoxicating substances, although in some cases quite the opposite is true. In those jurisdictions where drug deaths are considered accidents, double indemnity clauses may come into play. The families of victims dying from cocaine toxicity could, in some instances, be entitled to twice the face value of the decedent’s life insurance.

Parties injured in an accident may litigate to recover damages. The sobriety or intoxication of the deceased can be a factor in efforts to assign blame. And, of course, apparent accidental deaths may actually turn out to be suicides, or they may be natural deaths occurring in circumstances that suggest an accident. When a driver becomes incapacitated by a heart attack, for example, and loss of control results in an accident, toxicological studies may play a part in the investigation. Detection of intoxicants, together with other evidence, may indicate that an apparent accident was actually intentional. For example, finding large quantities of a drug in a deceased person’s stomach suggests that an overdose was intentional (i.e., suicide) rather than accidental.

If post-mortem investigation fails to detect carbon monoxide in the blood of a burn victim, or soot in the airway, it may be that the victim had already died when the fire started. Such cases may be deaths from natural causes, or attempts to destroy evidence of a murder. Further investigation may discover evidence of illness or trauma. Workplace accidents must always be investigated for the possible involvement of alcohol or other drugs, since there are likely to be insurance claims against the employer. If the victim is shown to have intoxicants in the body, the employer may be held blameless. Another aspect of workplace-related accidents concerns exposure to toxic chemicals. The potential for such exposures varies with the nature of the business. If exposure to a toxic

chemical is alleged or suspected, investigators should obtain a list of chemicals in the workplace, and the toxicology laboratory of the medical examiner should analyze for those chemicals whose toxicity is consistent with the circumstances of death.

12.1.3.4 Natural Deaths

Apparent natural deaths may or may not require toxicological study. If the autopsy clearly reveals the cause of death, and no history of drug or alcohol misuse is known, the pathologist may decide that further toxicological study is not necessary.^{23,25} Sometimes studies are ordered to evaluate compliance with required pharmacotherapy, such as measurement of anticonvulsant drug levels in an person with epilepsy who has a seizure and then dies. When the apparent cause of death may be related to drug or alcohol misuse, testing should be done to determine whether or not relevant drugs are present. For example, acute myocardial infarctions, cerebral hemorrhages, ruptured berry aneurysms, and dissecting aortic aneurysms are often associated with recent cocaine use. Such cases should be tested for cocaine and other drugs, particularly when this occurs in young people or when there is a history of drug use. A diagnosis of alcoholism should call for a blood alcohol analysis.

The diagnosis of sudden infant death syndrome (SIDS) is a diagnosis of exclusion. All apparent SIDS cases should be tested for alcohol and other drugs. Child abuse can include drugging a restless infant, where even a small dose of drug may be fatal.

When there is any uncertainty regarding the cause of death, testing should be done to rule out an overdose. Terminally ill people sometimes commit suicide, and hospice patients are occasionally poisoned by their caregivers. When samples for apparent natural deaths are submitted to the toxicology laboratory for testing, unrecognized poisoning cases are sometimes discovered.

12.1.3.5 Unclassified, Undetermined, or Pending

When the cause or manner of death remains elusive at the completion of investigations and autopsy, the case is left unclassified, pending further studies.^{4,23} Additional inquiries, microscopic examinations, and toxicological studies are initiated to find sufficient evidence for a diagnosis. The primary goal for the toxicology laboratory is to determine whether or not toxic substances are present in the deceased in sufficient quantities to kill. If a probable toxic cause of death is identified, the laboratory gathers additional evidence to assist the pathologist in deciding how it was administered, and estimating how much was used, and how long before death. The results of toxicology testing are considered along with other evidence to formulate an opinion regarding the manner of death.

12.1.3.6 Pending Toxicology (Overdose)

Death by poisoning or overdose may be accidental, suicidal, or homicidal.^{15,20,23,25–27} Various clues indicating poisoning may be observed during the autopsy. In some cases, a large amount of partially degraded medicinal tablets is found in the stomach, esophagus, mouth, and nostrils, or a typical strong smell of alcohol is noticed. However, other unusual odors or abnormal colors of stomach contents, urine, or tissues, and specific lesions may suggest to the experienced forensic pathologist that a drug or poison was the cause of death. Evidence from the death scene, such as a suicide note or empty containers, may point to a poisoning or drug overdose in some cases. However, most drug-related deaths do not leave such telltale markers as those found in heart attacks, cancer, or trauma. Often the only clue from the autopsy is pulmonary congestion and edema. The pathologist calls upon the toxicology laboratory to confirm the suspicion by identifying the poison or poisons and gathering enough quantitative data to support a conclusion that the detected poison was sufficient to cause death.

In addition, the laboratory may sometimes be able to shed light on the issues of how much was taken and the route of administration. The assignment of manner of death is based on the totality of the evidence, including the pharmacology and toxicology of the substance, the route of administration and quantity taken, the social and medical history of the deceased, and evidence collected from the death scene.^{7,20,28,29} Drug-related death certification is by a process of compilation and evaluation of all findings during the death investigation, where elimination of a number of other possible causes of death (COD) is as important as the detection of a toxic substance in sufficient concentrations to have caused or contributed to the death.²⁸

12.1.4 The Toxicology Examination

The toxicologic investigation typically begins with the preliminary identification of drugs or chemicals present in post-mortem specimens.^{30–39} Confirmatory testing is then performed to conclusively identify the substance(s) present in the post-mortem specimens. In a forensic laboratory, positive identification must be established by at least two independent analyses, each based on a different analytic principle. The next step in the process is to determine the quantity of substance in the appropriate specimens. Identifying drugs in waste fluids, such as bile and urine, is a useful undertaking, but quantifying drugs in these fluids usually has limited interpretive value. Drug quantification in peripheral blood, along with quantification in samples from liver, gastric contents, or other specimens, as dictated by the case, provides more meaningful interpretive information. Therapeutic and toxic ranges have been established for many compounds,²⁸ but it should be recognized that “therapeutic” concentrations rarely can be determined in the post-mortem setting.⁴⁰

All cases cannot be tested for all drugs. A number of factors, some not immediately obvious, determine what kind, and how many, tests will be done. The importance of the medicolegal classification of death and specimen collection has already been mentioned. But other factors, such as geographic patterns of drug use and laboratory capabilities, must also be considered.

Occasionally, mere detection of a drug is sufficient. But, in the case of some prescription medications, the actual amount present must be quantified. A request for “therapeutic” drug analysis may be made even if the autopsy has already determined the cause of death. If a history of seizure is obtained, the pathologist may request an antiepileptic drug screen to determine whether or not the person was taking any such medication. The same holds true for, e.g., theophylline in individuals with asthma. An individual who has committed suicide may have been prescribed therapeutic drugs for depression or other mental illness. A test for these drugs may indicate the degree of patient compliance. In forensic toxicology, a negative laboratory result carries the same weight as a positive result.

12.1.4.1 Poisons

Often the nature of a suspected toxin is unknown. This type of case is termed a “general unknown.”^{41,42} In cases of this nature, a full analysis of all available specimens by as many techniques as possible may be required to reach a conclusion. The most common approach involves first testing for volatile agents, and then performing drug screens. The drug screen is usually confined to those drugs that are commonly seen in the casework. When the most common substances have been ruled out, the laboratory proceeds to test for more exotic drugs and poisons.

12.1.4.2 Comprehensive Toxicology Screening

It is impossible to consider the topic of forensic toxicology without discussing analytical toxicology in detail.^{43–46} Screening methods should provide presumptive identification, or at least class identification while also giving an indication of concentration. An adequate screening protocol, capable of detecting or eliminating the majority of the commonly encountered toxins, usually

requires a combination of three or more chemically unrelated techniques. In general, some toxins are so common that, no matter the type of case, they should always be included for analysis; e.g., ethanol, salicylate, acetaminophen, sedatives, hypnotics, and other drugs such as cocaine, opiates, and antidepressants. All screening tests that are positive for substances relevant to the case must then be confirmed, and analytes of significance submitted for quantification in several tissues. Later sections in this chapter discuss testing methods and how they are combined to yield effective analytical strategies.

12.1.4.3 Case Review

During the toxicological investigation, each case is subjected to periodic review, its status evaluated, and the need for additional testing determined. Based on what is known about the death and the specimens available, a panel of screening tests is designed to quickly detect or rule out the most common drugs and, when appropriate, poisons.^{33,37,38,43,47} New tests may be ordered to expand the initial search, or to confirm preliminary findings.

The flow of information in forensic toxicology must be in two directions⁴⁸ — from pathologist to laboratory, then back to the physician who will integrate all of the findings. Laboratory personnel must effectively communicate with the pathologist concerning the scope (and limitations) of the services they can provide, suggest the proper selection of specimens, and assist with interpretation of the results. In particular, when drug screens are used, the pathologist should know which drugs they cover — and which drugs will go undetected. To operate effectively, the toxicologist must be provided with enough information about the history and autopsy findings to rationally select the most appropriate tests.

12.1.4.4 Quality Assurance

Each laboratory must formulate and adhere to a quality assurance (QA) program. QA provides safeguards to ensure that the toxicology report contains results that are accurate and reproducible, and that the chain of custody has been preserved. A written QA plan sets out the procedures employed to ensure reliability, and provides the means to document that those procedures were correctly followed. The laboratory's strict adherence to a proper QA program induces confidence in the laboratory's work product and prevents or overcomes potential legal challenges. Before a new or improved method is introduced into a laboratory, it must be selected with care and its performance must be rigorously and impartially evaluated under laboratory conditions.

12.1.4.5 The Toxicology Report

When all toxicological testing is completed, the results are summarized in a report that is sent to the pathologist. This report becomes a part of the autopsy report. It specifies the name of the deceased, if known, and the medical examiner case number. The specimens tested, the substances detected in each specimen, and the measured concentrations of those substances are presented in tabular form. The report should also list substances tested for, but not found, especially if they were named in the toxicology request. If any drug was detected, but not confirmed, a note to that effect should be on the report. In addition, any information about the specimens, such as the date and time of collection of ante-mortem blood or any unusual condition of a specimen, should also be noted on the report. Because of the well-known difficulties associated with the post-mortem redistribution of many drugs, the report should always indicate where in the body the blood specimen was obtained. Toxicology reports are usually signed or initialed by the issuing toxicologist, and in some jurisdictions may be signed by the pathologist as well.

12.1.4.6 Toxicological Interpretation

All substances are poisons; there is none which is not a poison. The right dose differentiates a poison and a remedy.

Paracelsus (1493–1541)

Poisons and medicines are oftentimes the same substance given with different intents.

Peter Mere Latham (1789–1875)

The significance of the reported results must be explained, often to a jury.^{5,28,43,48–51} The pharmacology, toxicology, local patterns of drug abuse, and post-mortem changes all can affect toxicological results. In any given case, a toxicologist may be asked the following questions (even though a definitive answer may not be possible in all instances):

1. What was taken, when and how?
2. Was the drug or combination of drugs sufficient to kill or to affect behavior?
3. What are its effects on behavior?
4. Does the evidence indicate if a substance was taken for therapeutic purposes, as a manifestation of drug misuse, for suicidal purposes or was it administered homicidally?
5. Was the deceased intoxicated at the time of the incident that caused death?
6. How would intoxication by the particular drug manifest?
7. Is there any alternative explanation for the findings?
8. What additional tests might shed light on the questions?

12.2 SPECIMEN SELECTION, COLLECTION, PRESERVATION, AND SECURITY

Bradford R. Hepler, Ph.D. and Daniel S. Isenschmid, Ph.D.

Toxicology Laboratory, Wayne County Medical Examiner's Office, Detroit, Michigan

Specimen selection, collection, preservation, and security place unique demands on the post-mortem forensic toxicologist. The quality of results expected from the post-mortem laboratory today is high and reflects the research advances and continued improvements in instrumentation and analytical methods seen since the origins of modern forensic toxicology in the early 20th century.^{1–3} However, it must be recognized that — even with technological advances — accurate, forensically defensible results are predicated on the quality and type of specimens provided, and the documentation of each specimen's origin and history. As important are issues relating to security and evidence control during the collection and storage process. Finally, in considering data available from publications and databases, it is important to recognize that the quality and the “comparability” of data between institutions are only as good as the consistency of approach in specimen collection, storage, and analysis between these organizations.

Many major references in forensic pathology have, each in their own manner, sought to provide information about specimen collection issues.^{1,4–9} More recently, the literature has focused on novel and more intriguing issues such as post-mortem release and/or redistribution of drugs from tissues into blood as mechanisms that can lead to legitimate debates about the meaning of a reported value.^{10–17} Thus, even an analytically “accurate value” may be subject to misinterpretation when the drug concentration in a single blood specimen is used to explain the circumstances surrounding a drug intoxication death, particularly when the drug concentrations are not excessively high or low. This and other specimen collection and documentation issues are the subjects for discussion in this chapter.

12.2.1 Chain of Custody

One major difference between forensic and clinical toxicology is that institutions performing forensic work are held legally accountable for documenting the handling of specific evidence within the organization. This means that all evidence associated with a specific case must be kept in a secure area at all times and be accounted for during its lifetime by using a record or chain of custody (COC).

Documentation should include *who* handled the evidence, *what* evidence was handled, *when* and *why* the evidence was handled, and *where* the evidence was located at all times. This documentation is central to the demonstration that the evidence has remained intact, and not been adulterated, changed, mishandled, or misplaced in any fashion that would compromise its integrity. Evidence ties together people, places, actions, and things, which have important impact on circumstances surrounding events in which individuals are held legally accountable. In criminal actions the importance of the evidence may truly involve a “life or death” determination, while in civil litigation large sums of money or property may be at stake.

The biological specimens collected during the autopsy are evidence and must be legally accounted for. Specimens must be maintained in secure, limited-access areas at all times with access restricted to only those individuals designated in the institution’s standard operating procedure. Specimen handling has been and will continue to be legally scrutinized by the courts. Properly maintained COC documentation rules out any period of time in which a specimen may be left vulnerable to adulteration or tampering. Failure to properly document the COC may compromise not only the integrity of the specimen, but also the credibility of the institution handling the specimen.

Labor-intensive documentation can be tedious and a natural deterrent to the consistent maintenance of records, including the COC. The use of computers for documenting COC and other specimen transactions within the post-mortem forensic toxicology laboratory has recently been demonstrated.^{18–20} The ability of the computer to routinely maintain and monitor predictable and consistently occurring events make it an ideal tool for tracking of forensic events.

12.2.2 Specimen Collection

12.2.2.1 Specimen Containers

There are several unique challenges to collecting post-mortem forensic toxicology specimens compared with specimen collection in other forensic toxicology disciplines such as human performance toxicology and employment drug testing. Post-mortem specimen quality can be quite variable, making specimen collection and subsequent reproducibility in aliquoting of the specimen difficult at times. Specimen quantity, or availability, will vary considerably from one case to another, yet the laboratory must attempt to provide a comprehensive toxicological analysis for a general unknown. In the latter regard, detection limits are pressed, and trace findings may have a major bearing on issues of compliance and proper patient care in hospitalized or extended care facilities and the potential for civil litigation. The use of appropriate specimen containers and preservatives can be critical in the toxicologists’ ability to ultimately identify a substance in a given specimen.

Usually, the best container to utilize when collecting and storing post-mortem biological fluids is glass.^{1,9,21} Glass is inert, does not contain any plasticizer contaminants, and maximizes storage space. Plasticizer contamination is further reduced with Teflon-lined caps. If drug concentrations of less than 0.010 µg/mL are expected, silation of glassware may be indicated.¹ Disposable Pyrex glass culture tubes are suitable for long-term frozen storage and come in a variety of sizes. It is important that the container size chosen for each specimen will allow it to be as close to full as possible in order to minimize concerns about oxidative losses due to air trapped in the top of the container, volatile drug evaporation, and “salting-out” effects from preservatives that may be added to the tube.¹ Generally, 50-mL culture tubes represent the best choice for blood and urine specimens.

Smaller tubes (e.g., 15, 20, and 30 mL) can be used for the collection of small amounts of blood, vitreous humor, and bile specimens.

Most types of plastic containers are suitable for the collection of solid tissue specimens and gastric contents. The nature of solid tissue reduces direct contact with the plastic container, and the relative amount of drug(s) present in gastric contents will minimize the influence of plasticizer interference.

The principal argument that can be made against glass containers is the possibility of breakage. However, this can be minimized by using appropriate storage racks and carrying totes. Some laboratories have successfully used plastic containers by identifying a product that reduces plasticizer contribution and adsorption of drug to the container. Nalgene® containers have been recommended for collection of post-mortem biological fluids.²² While drug stability in these containers was not determined to be a problem, the evaluation of contaminants was not reported. Whether a facility chooses glass or plastic, it is important that the laboratory carefully evaluate the container before routinely collecting specimens in it. The nature and potential for contamination can be evaluated by analyzing drug-negative biological fluids stored over time in the container. In addition, the plastic must be chosen carefully to ensure that it does not crack when frozen. For example, polystyrene is subject to cracking under these conditions whereas polypropylene is not.

12.2.2.2 Specimen Preservatives

Blood specimens should be preserved by adding 2% w/v sodium fluoride to the collection container. Sodium fluoride is added to inhibit microorganism conversion of glucose to ethanol, microorganism oxidation of ethanol,^{23,24} post-mortem conversion of cocaine to ecgonine methyl ester by cholinesterases,²⁵ and enzymatic loss of other esters such as 6-acetylmorphine.^{1,26} Esters, subject to alkaline hydrolysis, are more stable in post-mortem blood than ante-mortem blood because the pH of blood falls after death; therefore acidification of blood is not indicated. Some laboratories may choose to add an anticoagulant such as potassium oxalate, EDTA, or sodium citrate at a concentration of 5 mg/mL in addition to the fluoride preservative.^{21,23,24} Preservatives and anticoagulants may be added to collection containers designated for blood ahead of time. However, if only a small amount of blood is collected, the excess fluoride may affect headspace volatile assays by altering the vapor pressure of the analyte.¹¹ Ideally, one preserved and one unpreserved blood specimen should be taken for comparison, if needed.²²

Once collected, blood specimens should be stored in tightly sealed containers at low temperatures (4°C short term and -20°C long term). The low temperatures inhibit bacterial growth and generally slow reaction kinetics such as the conversion of ethanol to acetaldehyde.²⁵ In addition, an aliquot of preserved blood, sufficient in quantity to fill the secondary container, should be removed from the primary specimen at the time of specimen accessioning and stored at -20°C in a frost-free freezer. This aliquot should be saved for the quantitative confirmation of unstable analytes such as cocaine and olanzapine and for ethanol reanalysis, if needed.

Specimen preservatives are generally not required for other specimens (e.g., urine, bile, vitreous, tissues, etc.); however, to all samples subject to alcohol analysis, sodium (or potassium) fluoride should be added. As for blood, these specimens should be stored sealed at 4°C until testing is completed and then frozen at -20°C if long-term storage is required.

12.2.3 Sampling

Biological fluids are collected using new or chemically clean hypodermic syringes using appropriate needle gauges and lengths for the specimen to be collected. One needle and syringe should be used per specimen taken. If syringes and needles are to be reused, then care must be taken to scrupulously clean and disinfect these devices between uses. A typical cleansing procedure should include a minimum of 30 min of soaking in a disinfectant, e.g., 10% solution of household

Table 12.2.1 Guide to the Collection of Routine Toxicology Specimens

Specimen	Amount	When to Obtain	Comments
Blood, heart	50–100 mL	Always	Identify source; preserve with 2% sodium fluoride and potassium oxalate; reserve an aliquot without preservative, if possible
Blood, peripheral	5–10 mL	For complete toxicology testing	Identify source; use femoral or subclavian blood if possible
Blood, clot	Whole clot	Trauma cases	
Urine	All	Always	Submit any quantity, even if <1 mL, for immunoassay screening
Bile	All	Always	Tie off gallbladder to reduce contamination; collect prior to liver
Vitreous humor	All	Always	Combine fluid from both eyes into a single tube
Gastric contents	All	For complete toxicology testing	Tie off stomach to prevent contamination of other viscera; note total volume
Liver	50 g	Always	Identify source; deep right lobe preferred
Kidney	50 g	Metals, ethylene glycol	
Spleen	50 g	CO, CN	Very useful when blood not available in fire deaths
Brain, fat	50 g	Lipophilic drugs	Brain may be especially useful in infant drug deaths
Lung	50 g	Volatile poisons	Collect in sealed container; collect tracheal air as well
Hair	Pen-sized bundle	Drug history, metals	Identify distal and proximal ends

Note: Biological specimens should be kept at refrigerated temperatures (4°C) for short-term storage (up to 2 weeks) and at frozen temperatures (–20°C) for long-term storage. An aliquot of preserved blood should be frozen immediately for analysis and preservation of less stable compounds.

bleach in water (0.5% w/v sodium hypochlorite in water), followed by washing with a non-ionic detergent and rinsing with copious amounts of clean water. Additional disinfection can be performed using an autoclave operated under proper quality control guidelines. The College of American Pathologists recommends that instruments be autoclaved at the usual steam autoclave pressure of 15 lb for 45 min. These conditions are suitable for most pathogens; however, higher pressures and temperatures for longer times (approximately 2 h) are necessary if the rare Creutzfeldt–Jakob disease is of concern.²¹ For all this effort, it would seem that disposable needles and syringes are the easiest and most time effective and efficient approach for sampling while reducing the possibility for specimen contamination.

Additionally, autopsy staff must maintain the cleanliness of the specimen container as they collect the specimen. All spillage on the outside of the container should be rinsed off and decontaminated using 10% bleach solution.

Collection techniques are discussed below by specimen type. Table 12.2.1 provides a summary of the information discussed in detail in the text.

12.2.3.1 Blood

Whenever possible, post-mortem blood specimens from two sites, heart and peripheral, should be collected at every autopsy. If no autopsy is performed, then only peripheral blood should be collected.

Heart blood specimens should be taken by needle aspiration using a suitable hypodermic syringe. To obtain a proper cardiac specimen, the pericardial sack must be opened, the pericardium removed, the heart dried, and the blood specimen removed by syringe. Blood from the right chamber is preferable, but regardless from where blood is collected it is essential to label the site from which it was taken.²¹ At least 50 mL should be collected, more if possible.

Peripheral blood specimens are usually obtained from the femoral vein. Leg veins are preferred to veins of the head and neck due to the anatomical presence of a larger number of valves that

resist blood movement from the intestines.²³ The peripheral blood specimen should be taken using a clean or new 10- to 20-mL hypodermic syringe. Do not “milk” the leg in order to increase specimen volume. If possible, up to 10 mL of peripheral blood should be collected. The source of the peripheral blood specimen should be noted on the specimen container.

As discussed elsewhere, blood clots should be collected in cases of head trauma or if other blood specimens are not available. Because of the strong possibility of contamination, thoracic and abdominal cavity blood should be avoided unless no other blood is available. If collected, they should clearly be labeled as to the source or origin.

12.2.3.2 Urine

During autopsy, urine specimens should be taken directly from the bladder by insertion of a clean/new hypodermic needle into the bladder. For non-autopsied cases the needle may be inserted directly through the lower abdominal wall, just above the pubic symphysis.⁹ If possible, up to 100 mL of urine should be acquired. In cases where the bladder appears to be empty, it is important to aspirate as much urine as possible from the bladder and the ureter. Bladder washings using a minimum amount of clean water (or saline) would be desirable in the absence of any urine. The specimen container should clearly identify and indicate the nature of this specimen, and the amount of water/saline utilized. As little as 50 µL of urine can be useful for some applications such as chemical spot tests and immunoassay testing.

12.2.3.3 Bile

Following the removal of the organ block during the autopsy process, bile is aspirated from the gallbladder using a clean/new hypodermic syringe. If there is any possibility of contamination, the gallbladder should be tied off and removed from the organ block so that the bile may be collected away from the potential source of contamination. Up to 15 mL of bile should be collected and placed into a properly labeled screw-capped glass culture tube.

12.2.3.4 Vitreous Humor

Vitreous humor specimens are obtained by direct aspiration from each eye using a 5- to 10-mL syringe and 20-gauge needle. The needle should be inserted through the outer canthus, until its tip is placed centrally in the globe. Vitreous humor can be aspirated from the globe by application of gentle suction. Vacuum tubes and heavy suction should be avoided to prevent specimen contamination with retinal fragments and other tissue. With proper technique 2 to 3 mL of fluid can be removed from each eye in an adult, while up to about 1 mL of specimen may be removed from a newborn.²⁷ Once the vitreous specimen has been removed from the eye, an appropriate amount of saline can be injected back into the eye in order to reproduce the cosmetic integrity of the eye. Vitreous humor specimens obtained from both eyes may be combined in one properly labeled specimen container.

12.2.3.5 Gastric Contents

Because gastric contents are not homogeneous, and because the total volume of gastric fluid is critical in the interpretation of positive findings, the entire contents of the stomach should be collected. If this is not possible, then the total volume present must be noted and provided with the specimen to the laboratory. The prosector should tie off the stomach ends before removing it from the organ block. The stomach should be opened away from other specimens and tissues, in a manner to avoid contamination of other viscera.

12.2.3.6 Hair

Hair is preferably collected from the posterior vertex or the back of the skull, where the average hair growth rate is fairly constant, and has been extensively studied.²⁸ The size of the sample to be collected is dependent on the purpose of the analysis. If a segmental analysis is desired, hair from a 1 × 2 cm area will typically yield about 50 mg of hair/cm segments, which is the amount used for many GC/MS or LC/MS methods reported. Additional samples have to be collected if several analyses with different extraction techniques are desired. One strategy is to collect one sample for screening, and additional samples for confirmation analyses,²⁹ should the screening come out positive.

In cases with a suspicion of a recent poisoning, analysis of plucked hair may be rewarding, since there is an interval for most drugs during which blood, urine, and cut hair may all be negative, but where the intradermal portion of the hair may harvest traces of the drug. The most common scenario is, however, that the hair analysis is used as a supplementary tool to disclose or confirm previous drug use. Cut hair is then usually preferable since hair roots, often containing high amounts of drugs from an acute intake, are then excluded. Unfortunately, it is difficult to avoid disalignment of a hair sample no matter how carefully the hair is cut from the scalp. An easy way to align the hair strands is to put the sample collected into a small Eppendorff tube with the cut end first and use tweezers to adjust the hair strands. If the time for exposure is not an issue, this procedure is not necessary, and further, smaller hair samples may suffice.

Directly after collection, a convenient means to preserve the alignment, and to keep control of the scalp end, is to put the sample into a small piece of aluminum foil, which is folded once or twice. Putting hair into folded paper should be avoided, particularly regarding plucked hair, since the sticky hair roots will become fixed to the porous surface of the paper, and the strands will break at variable distances from the root. Hair that has been soaked with blood should first be washed with water and then dried before sampling. It is wise to make a note that such contamination has occurred if it turns out that the blood contains high levels of drugs.

12.2.3.7 Tissues

When collecting tissue, a minimum of 50 g should be collected. Each specimen collected should be put into its own properly labeled airtight container. If inhalants are suspected, it is important to collect and seal the specimen in a container as soon as possible after the body has been opened. Because of the possibility that portions of the liver can be contaminated by post-mortem diffusion of drugs from the gastric contents, only liver from deep within the right lobe should be collected.³⁰ Additionally, bile should be collected prior to the liver specimen, to prevent specimen contamination.

12.2.3.8 Labeling

The first step in the specimen collection process (including evidence collection) is ensuring that the specimen containers are labeled appropriately. Without attention to this detail all other activities that occur with the specimen(s) are suspect. First, the collector must only be working with one specimen at a time. Second, specimens collected should *never* be placed into an unlabeled container. The collector must ensure that the container is labeled so that it can be read prior to the placement of the specimen into the container. As a minimum, the label should include the following information: (1) institutional case number identifier; (2) name or other identifier; (3) date and time of collection; (4) signature or initials of the collector; (5) specimen type (blood, liver, kidney, etc.) and where collected, when applicable (heart blood, femoral blood, etc.). Finally, tamper-resistant tape with the collector's initials and the collection date should be placed over the specimen lid and container to document specimen integrity. Alternatively, all of the samples collected for a given case may be placed in a tamper-evident container labeled with the case number and name. This

protocol is particularly useful in institutions with larger caseloads where specimens may not immediately be transferred to the toxicology laboratory.

12.2.4 Selection of Post-Mortem Specimens

The choice of specimens available in a post-mortem forensic toxicology investigation can be numerous and variable. Specimens may be selected based on case history, institutional policy, and availability for a given case. Generally, the specimens routinely collected from cases in which an autopsy was performed include blood from both peripheral and cardiac sources, all urine and bile available, vitreous humor, all available gastric contents, and tissues (particularly liver).² However, because the autopsy allows a one-time opportunity to collect as many specimens as may be needed to complete the toxicological investigation, it is suggested that as many specimens be obtained as is feasible for the institution.

In cases where no autopsy is performed, only peripheral blood, urine, and vitreous humor are collected. Heart blood should be avoided due to the potential of contamination by esophageal contents when performing a blind stick.^{31,32}

On some occasions a medical examiner or coroner's case may have had a significant survival time in the hospital prior to death. In cases where hospital survival time exceeds 24 to 48 h, the value of post-mortem specimens diminishes considerably. This is especially true if there are allegations that a death may be drug related. Under these circumstances, hospital admission specimens (blood and urine) taken prior to significant therapeutic intervention can be invaluable in the documentation and support of this history. It is important that the post-mortem toxicology laboratory physically obtain these specimens (under COC) for reanalysis, since the results available from the hospital are frequently unconfirmed screening results.

Decomposed, skeletonized, or embalmed cases present unique challenges for the forensic toxicologist. The possibilities for specimens in some of these cases are limited only by availability, analytical capabilities, and sometimes imagination, of the toxicology laboratory. Some of these unusual specimens are discussed later in this section.

12.2.4.1 Blood

Blood is the specimen of choice for detecting, quantifying, and interpreting drug concentrations in post-mortem toxicology. Historically, most of the meaningful data derived from the literature was determined in blood.³³ Despite concerns about post-mortem redistribution of drugs from tissues to blood, some aspects of interpretation remain straightforward. A negative result below a defined limit of detection for a given analyte can be readily interpreted as lack of acute exposure to that analyte or noncompliance in the case of therapeutic agents. Conversely, blood drug concentrations that exceed therapeutic (or, for some drugs, toxic) concentrations by 10 to 20 times are still consistent with intoxication or death (barring an obvious contamination problem). In addition, the higher the parent drug-to-metabolite ratio, the more likely acute intoxication is a factor. This is especially the case when multiple drug analytes are involved, and in cases involving ethanol.

Interpretation becomes especially difficult in cases where drug analytes known to undergo post-mortem redistribution are determined to be present in a heart blood specimen at concentrations ranging between the upper therapeutic limit and the lower limit where intoxication or death has been reported. In these cases, analysis of a peripheral blood specimen may be critical in determining the role that the drug may have played in the decedent. Although drug concentrations in cardiac blood generally rise due to post-mortem drug redistribution, and peripheral blood drug concentrations tend to remain constant, this is not always the case.^{13,34,35} Thus, results from a single post-mortem blood specimen, whether cardiac or peripheral, may be difficult if not impossible to interpret. Since cardiac blood is usually more plentiful than peripheral blood, many laboratories perform initial toxicological tests on cardiac blood, reserving the peripheral blood specimens for

cases where additional context is needed for interpretation. Regardless of the blood samples available for analysis, it is important for the toxicologist to appreciate that the material collected as “blood” at autopsy is not the same specimen collected in an ante-mortem venipuncture and clinically based pharmacokinetic principles may not be applicable to post-mortem cases.

Following injury or trauma to the head, blood clots from the brain cavity (subdural, subarachnoid, and/or epidural) should be collected in properly identified containers and saved for the laboratory. These materials are potential “time capsules,” which are generally poorly perfused, and may reflect drug or alcohol concentrations closer to the time of injury. These specimens become more important as accurate knowledge of the post-injury survival time increases. Blood clots may also be useful for documenting preexisting drug use prior to hospital therapy. Most laboratories routinely analyze alcohol on these specimens, reserving analysis for additional drugs if indicated. Thoracic and abdominal cavity blood should be collected for analysis only if blood or uncontaminated blood clots cannot be obtained from any other area. These “blood” specimens tend to be contaminated by and contain large numbers of microbes. Additional contamination from gastric contents is also possible. Nevertheless, qualitative documentation of presence of given analytes is of importance and value in death investigations with respect to compliance and exposure issues.

12.2.4.2 Urine

Urine collected at autopsy has the greatest potential of any specimen to provide the toxicologist with qualitative ante-mortem drug-exposure information. The urine matrix is generally devoid of circulating serum proteins, lipids, and other related large-molecular-weight compounds due to the renal filtration process, simplifying preparation of the specimen for analysis. The accumulation of drugs and their metabolites in urine results in relatively high drug concentrations, facilitating detection of an exposure to a potential poison. Immunoassays and non-instrumental spot tests can be performed directly on the urine specimen for the analysis of certain drug classes. Detection times for drugs in urine can vary from 24 h to as long as a month, depending on the drug. Thus, except for acute drug deaths where survival time is less than an hour and drugs may not yet have been excreted into the urine, urine provides an ideal matrix for the detection for the widest variety of compounds.

Positive identification of drugs in the urine indicates past drug use, but does not indicate when or how much drug was ingested. To interpret the context of exposure, blood should be tested for the analytes found in the urine. In cases where death is suspected to have occurred rapidly due to drug ingestion, as might be suggested by the presence of a needle in the decedent’s arm at the time of death, negative urine drug findings may be consistent if blood drug concentrations are very high.

12.2.4.3 Bile

Bile is another fluid that should be collected at autopsy as a matter of course since many drugs and drug metabolites have been demonstrated to accumulate in this specimen.^{1,9,21,36,37} The qualitative finding of the presence of drug and/or metabolites in this specimen is important, for documentation of historic exposures to specific agents and chronic drug-use history. In the absence of urine, bile has also been useful as an alternative specimen for alcohol analysis³⁸ and has been used in immunoassay screening after sample pretreatment³⁹ or without pretreatment using enzyme-linked immunosorbent immunoassays.⁴⁰ Historically, bile has most often been used in the determination of opiates in general and morphine in particular.^{1,36,37} More recently, it has been noted that many drugs are found to accumulate at concentrations significantly higher than those in blood.³⁹ With an appropriate sample cleanup, bile is a useful specimen for the analysis of a wide variety of drugs and their metabolites, including benzodiazepines.

12.2.4.4 Vitreous Humor

Vitreous humor plays an important role in helping resolve many issues in a post-mortem examination. Because of this, it should be collected in all cases when possible, including cases where no autopsy is performed. Vitreous humor, by virtue of its protected environment inside the eye, is less subject to contamination and bacterial decomposition. As a result it may be used to distinguish ante-mortem alcohol ingestion from post-mortem alcohol formation and may provide the only opportunity to establish an ante-mortem ethanol concentration in embalmed bodies.^{23,24,41–43} Additionally, because vitreous humor is contained in a peripheral compartment, there is a delay in both the uptake of drugs and alcohol into this fluid as well as a delay in the excretion process.

It has been observed that vitreous drug concentrations often reflect circulating blood concentrations 1 to 2 h prior to death and that any drug found in the blood will be detected in the corresponding vitreous specimen given analytical techniques of sufficient sensitivity.⁹ Although these findings suggest that vitreous humor analysis following positive blood findings might be useful to aid in the interpretation of blood drug concentrations, more research needs to be performed. Studies comparing vitreous humor and blood ethanol concentrations yielded a wide variety of ratios of vitreous humor to blood ethanol.⁴² If such diversity is seen for an analyte that demonstrates minimal post-mortem redistribution effects, attempting to use vitreous humor drug concentrations to aid in interpreting heart blood drug concentrations may prove difficult.¹¹ Despite these concerns, vitreous humor is the best specimen from which to evaluate post-mortem digoxin concentrations.²¹ However, the analysis of femoral blood in addition to vitreous humor is still recommended to provide the best context for an appropriate interpretation of ante-mortem digoxin toxicity.⁴⁴

Vitreous humor lacks the esterases that hydrolyze certain drugs and metabolites in blood and may be the specimen of choice to detect the metabolite of heroin, 6-acetylmorphine.^{45–48} Because 6-acetylmorphine is quickly hydrolyzed *in vivo* and *in vitro* (especially without the presence of sodium fluoride) to morphine in blood, the analysis of vitreous humor may be helpful in establishing whether a death occurred after heroin use. Similarly, cerebrospinal fluid may also be useful.^{48,49}

Vitreous humor has been shown to be particularly useful for the post-mortem analysis of glucose, urea nitrogen, uric acid, creatinine, sodium, and chloride. Measuring these analytes is important for documenting diabetes, degree of hydration, electrolyte balance, and the state of renal function prior to death. A recent article has reviewed the extent and breadth of chemistry analyte analysis applied to vitreous fluid, among other post-mortem specimens.²⁷

12.2.4.5 Gastric Contents

Oral ingestion is still the major route of drug administration for prescribed drugs and therefore a major compartment for the investigation of a potential poisoning. Drug overdoses, whether by accident or by intent, may readily be discovered through the analysis of gastric contents. In many cases undissolved capsules or tablets may be discovered, which may be useful for identification. In addition, illicit drugs are frequently smuggled by ingestion of balloons or condoms filled with the contraband. If these devices burst and an acute drug death occurs, evidence of these items may be seen in the gastric contents at autopsy.⁵⁰

A large quantity of the parent drug in the gastric content, relative to a prescription dose, are indicative of an oral drug overdose when supported by blood and/or tissue findings.⁵¹ However, the toxicologist is cautioned that low concentrations of drug in the stomach, especially drug metabolites and weak bases, may represent passive diffusion and/or ion trapping from the blood back into the stomach contents and may not be indicative of a recent oral ingestion of these agents. It is important to make a record of the total volume of gastric contents present in the decedent in order to calculate the total amount of the analyte present in the stomach. Since the gastric content is not a homogeneous specimen, ideally the entire specimen should be submitted to the toxicology laboratory for mixing before aliquoting.

The odor of gastric contents can potentially point to a specific agent that might otherwise elude routine detection in the toxicology laboratory. Cyanide ingestions produce stomach contents with the odor of bitter or burned almonds. Although not everyone is able to discern this odor, its presence is almost certainly indicative of a cyanide intoxication, and may be potentially hazardous in close quarters. Other characteristic odors include the “fruity-like” odor of ethanol and its congeners; the odor of airplane glue (xylene, toluene); cleaning fluid (halogenated hydrocarbons); carrots (ethylchlorovinyl);³² and garlic (organophosphate insecticides).³²

12.2.4.6 Tissues

Tissues commonly collected for post-mortem study include liver, kidney, brain, lung, and spleen. Tissues provide the best and most useful context with which to interpret blood findings. They may also be the only specimens available in decomposed cases. A large amount of data for drug findings in tissue exists, primarily for liver and kidney, and, to a lesser degree, brain, and lung.³³ Comparison is most often between heart blood findings and those in the liver, the site where many drugs are metabolized and for which the greatest amount of reference data is available. For example, in cases where the concentration of basic drugs in blood is high and ratios of liver to blood drug concentration exceed 10, a drug fatality is strongly suggested if no other interceding cause of death is present. Smaller ratios, even with high heart blood concentrations, tend to suggest a greater potential for post-mortem redistribution of drugs into the blood.

Analysis of tissue may be more appropriate than analysis of biological fluids for some analytes. In cases of heavy metal poisoning, kidney is a very useful specimen as heavy metals concentrate in it. In addition, structural damage to the kidney due to heavy metal or ethylene glycol exposure may be documented histologically. Spleen, an organ rich in blood, is useful for the analysis of compounds that bind to hemoglobin, such as carbon monoxide and cyanide. Frequently, in fire deaths where extensive charring is present, spleen may be the only useful specimen available to perform these assays. Lung tissue is particularly useful in cases where inhalation of volatile substances, such as solvents or Freon, is suspected. In addition, air may be collected directly from the trachea with a syringe and injected into a sealed vial to be used for headspace analysis.⁵² Brain, due to its high fat content, tends to accumulate lipophilic substances, such as chlorinated hydrocarbons, and other organic volatiles. Additionally, there is evidence to suggest that ratios of brain to blood cocaine are high in cocaine fatalities; thus cocaine deaths may be more readily interpreted through the analysis of both matrices.⁵³ Finally, because the brain is in a protected environment, it also tends to be more resistant to post-mortem decomposition.

The analysis of tissue is performed by weight. Usually, 1 to 5 g of tissue is shredded and homogenized with four parts of water (or saline) to generate a final dilution factor of 5. Recovery of drug from this homogenate has been found to be consistent with recovery of drug from post-mortem blood.⁵⁴ Drilling through the tissue with a cork-borer allows tissue to be sampled and weighed while frozen.⁵⁵ This method is easier and more precise than sampling wet tissue and is less malodorous when handling decomposed specimens.

12.2.4.7 Hair

Hair has a long history as a useful specimen in forensic toxicology. Traditionally, hair, along with fingernails, was the specimen of choice in determining chronic heavy metal poisoning such as arsenic, mercury, and lead. Heavy metals bind to sulfhydryl groups on the cysteine molecule to form a covalent complex. Keratin, found in large amounts in hair and nails, is an excellent source of cysteine, and therefore an ideal specimen for determining chronic arsenic and mercury poisoning. Interpretation of positive findings can be augmented by segmentation of the hair strands to assist in determining the time of exposure.^{56–58}

More recently, hair has been successfully used as a specimen from which chronic drug use may be determined.⁵⁹ Numerous drugs have been identified in hair including drugs of abuse^{60,61} and, more recently, various therapeutic agents.^{62,63} The usefulness of hair analysis in determining compliance remains controversial.⁶⁴ However, in post-mortem toxicology, segmental analysis can offer a temporal mapping of the drug abuse pattern, and such information may prove useful to identify possible hazardous drug combinations and to detect periods of abstinence that might indicate reduced tolerance to particular groups of drugs. In extremely decomposed or skeletonized cases where no other specimens remain, positive findings for drugs in hair may at least corroborate a history of drug use. The use of hair in workplace drug testing is controversial due to issues such as environmental contamination,⁶⁵ washing techniques,⁶⁶ sex or ethnic bias,^{67,68} the difficulty in performing quantitative analysis,⁶⁹ and establishing cutoff concentrations.⁷⁰ In the post-mortem setting these issues are not critical, and drug analysis for both pharmaceutical and illicit drugs in hair will most likely become more frequently applied following a growing appreciation of the supplemental information that such analysis may add to the interpretation of the routine toxicological results.

12.2.4.8 Bone and Bone Marrow

Bone marrow has not received a great deal of consideration as an alternative specimen in post-mortem toxicology. Because it is protected by bone, the highly vascularized tissue may be particularly useful when contamination of blood specimens is suspected in trauma cases. Research studies have been performed, primarily on rabbits, showing that linear relationships exist between bone marrow and peri-mortem blood drug concentrations for up to 24 h for many substances including tricyclic antidepressants, barbiturates, benzodiazepines, and ethyl alcohol.^{71–74} However, these studies were performed when the bone marrow was still fresh and moist. Although putrefaction is delayed in bone marrow, usually bone marrow is not considered as an alternative specimen in post-mortem toxicology unless other specimens are unavailable. Typically, at this stage of decomposition the bone marrow has transformed from spongy red marrow to a brown viscous liquid or paste-like substance, and it is unknown if any interpretation can be made from quantitative data.⁷⁵ However, drugs have even been identified in the bone marrow of skeletonized remains,^{76,77} and heavy metals have been identified in the bone itself.⁷⁸

12.2.4.9 Skeletal Muscle

Skeletal muscle is an often-overlooked specimen with many potential applications in post-mortem forensic toxicology. It meets many of the criteria of an ideal forensic specimen: it is relatively homogeneous, almost always available, and not easily contaminated. Studies have shown that drug concentrations in thigh muscle reflect drug concentrations in blood for many common basic drugs and ethyl alcohol, except in cases of an acute drug death where muscle drug concentrations may be lower than blood due to inadequate time for tissue equilibration.⁷⁹ The analysis of thigh muscle may be especially useful in cases where drugs suspected of undergoing post-mortem release are detected in the heart blood.⁷⁹ It is important that extremity muscle be collected, where possible, as drug concentrations in other muscles, such as abdominal muscle, increase with time while remaining constant in thigh muscle.^{80,81}

Because skeletal muscle is often well preserved despite advanced decomposition of other tissue, it may be useful as an indicator of post-mortem blood concentrations even in decomposed cases, although more studies need to be performed.^{81,82} Surprisingly, even parent cocaine, which is known to be unstable in blood, has been identified in numerous cases of decomposed, dried skeletal muscle.⁸³

The potentially useful data that may be obtained from the analysis of skeletal muscle have prompted some toxicologists to recommend that skeletal muscle be collected in all cases where drugs may be implicated in the cause of death.⁸¹ One disadvantage to skeletal muscle is the need

to homogenize the sample prior to analysis. However, this is true of many traditional specimens as well, such as liver and kidney. As more laboratories analyze skeletal muscle leading to the availability of additional data to aid in the interpretation of results, its potential advantages will outweigh any disadvantages.

12.2.4.10 Larvae

In cases of suspected poisoning where decomposition prevents traditional specimens from being obtained, homogenized fly larvae, usually of Calliphorid genus (blowfly), have proved to be useful alternative specimens in which drugs may be identified. Depending on temperature, larvae may be present as soon as 1 to 2 days after death. The first reported use of fly larvae in drug analysis occurred as recently as 1980 and involved a phenobarbital case.⁸⁴ Since then numerous drugs have been identified in fly larvae including barbiturates, benzodiazepines, and tricyclic antidepressants,⁸⁵ opiates,⁸⁶ cocaine,⁸⁷ and the organophosphate, malathion.⁸⁸

The choice of where larvae are best collected from the body needs further study. Interpretation of positive findings seem to be most useful if the larvae are collected at the site of their food source, such as any remaining muscle or liver, under the premise that drugs detected in fly larvae feeding on a body can only have originated from the tissues of that body.⁸⁹ This assumption seems to be supported by one study where a quantitative relationship was suggested between the morphine concentrations in the larvae and the livers on which they fed.⁹⁰ By contrast, other studies suggest that the analysis of fly larvae provides only qualitative data.^{85,86,91} However, in these studies larvae were collected from multiple sites and pooled before analysis. If larval drug concentrations are based on the tissue on which they fed,⁸⁹ these results are not surprising.

Studies using Calliphorid larvae have shown that the age of the larvae may also play a major role in determining whether drugs may be identified in them.^{91,92} By collecting larvae over a period of up to 11 days in cases of known suicidal drug overdoses, it was demonstrated that drugs were readily detectable in larvae through the third instar stage, but a precipitous fall in drug concentration was associated with pupariation after their food ingestion ceases. Similarly, larvae that had been feeding on drug-laden muscle for 5 days demonstrated a significant loss in drug concentration within 1 day of being transferred to drug-free tissue. This suggests that Calliphorid larvae readily eliminate drugs when removed from a food source. Thus it appears to be critical that larvae collected for drug analysis from a decomposed body be frozen and analyzed as soon as possible after collection. Even under refrigerated conditions, when larvae are in a state of diapause, slow bioelimination of drugs still occurs over the course of several weeks.⁹³ In addition, to eliminate surface contamination as a possible source of interpretive error, larvae should be washed with deionized water prior to analysis.

12.2.4.11 Meconium

Meconium, the first fecal matter passed by a neonate, has recently been given much attention because it is a useful specimen in which to determine fetal drug exposure. Issues relating to the screening and confirmation of most drugs of abuse in meconium have been reviewed.⁹⁴ While meconium analysis has principally been performed to assess *in utero* drug exposure in newborns so that treatment may begin as early after birth as possible, it may also be useful in determining drug exposure in stillborn infants. One study demonstrated the presence of cocaine in the meconium of a 17-week-old fetus, suggesting that fetal drug exposure can be determined early in gestation.⁹⁵

Unlike urine, which allows the detection of fetal drug exposure for only 2 to 3 days before birth, meconium extends this window to about 20 weeks. Most post-mortem toxicology laboratories are not currently performing meconium analysis. While potentially useful, there are several issues that must be considered. Because meconium forms layers in the intestine as it is being deposited,

it is not a homogeneous specimen. As with other nonhomogeneous specimens, such as gastric contents, it is important that all available specimens be collected and thoroughly mixed before sampling. Consideration should also be given to the fact that infants do not metabolize some drugs the way adults do. If commercial immunoassay screening kits are used that target metabolites found in adult urine, the ability to detect some drugs in meconium may be compromised.⁹⁶

12.2.4.12 Other Specimens

Many other specimens have been used in toxicological investigations. Any item with which a body or bodily fluid has been in contact is a potential candidate for the identification of drugs or poisons. Examples include tracheal air,⁵² blood stains on clothing,⁹⁷ soil samples collected at the site of a skeleton or decomposed body,⁹⁸ and even cremation ash.⁹⁹ Even though positive findings in these specimens are qualitative, there is at least the potential that this information can be useful in determining the circumstances of a death.

12.2.5 Nonbiological Evidence

Evidence found at a scene may provide additional information to assist in the toxicological investigation. Drug paraphernalia (cocaine spoons, cookers, bhongs, syringes, poppers, whipped cream propellant canisters, butane lighters, etc.) is suggestive of a possible drug-related death, or at least a history of drug abuse. Prescription drugs at a scene may be useful for compiling a list of suspected drugs, attending physicians, and pharmacy phone numbers. However, this evidence may be misleading as drugs found at a scene are frequently old, may not have been taken for years or due to patient compliance problems, or may be someone else's medication. Pain medication and tranquilizers, particularly important in drug deaths, are often prescribed to be taken on an as-needed basis, and thus subject to collecting in medicine cabinets. Counting the number of tablets or capsules in a prescription vial for consistency with the date of the prescription and dosage instructions may be useful, but has the potential for many variables including that of compliance. Additionally, empty medicine vials are not necessarily indicative of a drug overdose. Nevertheless, it is important that for a potential drug-related death, the role of the drugs found at the scene be ruled out by assaying for the agents of potential pharmacological significance.

Whether prescription vials are submitted to the toxicology laboratory is largely a matter of choice in a given jurisdiction. Since these items are evidence, it is often best that the police maintain them and provide a list to the laboratory. Unless the toxicology laboratory has specific experience in analyzing powders and syringes, or has jurisdiction over them, these items are best left for the crime laboratory to analyze, if needed.

In cases where poisoning is suspected, household products at the scene may provide key evidence for the toxicologist. Examples include aerosol containers in suspected inhalation deaths, rat and pest killers, insecticides and pesticides, caustics, windshield washer solvents, anti-freeze, Freon, etc. The garage, basement, or under-sink cabinets are common storage places for many of these items. Unlabeled containers holding solids or liquids, or more importantly, labeled containers that clearly hold a different product, may be the key to a poisoning case. These items, or an aliquot of them, should be provided to the toxicology laboratory, since they often contain analytes for which the toxicology laboratory does not test. The analysis of the product in question may provide mass spectral data and chromatographic information that can be correlated with findings in the biological matrix.

Suicide notes are often critical in determining whether drug intoxication is determined to be an accident or a suicide. However, the toxicologist is cautioned that if a suicide note identifies the suicidal agent or agents, toxicological analysis may reveal a different substance entirely.

12.3 COMMON METHODS IN POST-MORTEM TOXICOLOGY

W. Lee Hearn, Ph.D.¹ and H. Chip Walls, B.S.²

¹ Director, Dade County Medical Examiner Toxicology Laboratory, Miami, Florida

² Department of Pathology, Forensic Toxicology Laboratory, University of Miami, Miami, Florida

12.3.1 Analytical Chemistry in Post-Mortem Toxicology

Analytical toxicology is an applied science.^{1–4} Toxicologists must be familiar not only with the effects and toxic mechanisms involved in poisoning, but also with the metabolism of drugs, the chemical properties of parent drugs and their metabolites, and the composition of biological

Table 12.3.1 Comparison of Frequently Used Methods for Analysis of Biosamples

Method	Specificity	Sensitivity	Multiple Drugs	Identification:	Quantitative Analysis	Labor	Expertise
				Structural Analysis (Qualitative)			
Color tests	+	+	Yes	+	Some	+	+
UV-VIS	+	+	No	++++	Yes	++	++
IA	++	++	Some	No	Some	+	+
GC	++	++	Yes	++	Yes	++	++
TLC	++	+	Yes	++	No	+++	+++
HPLC	++	++	Yes	++	Yes	++	++
GC/MS	++++	++++	Yes	++++	Yes	+++	++++
AAS	+++	+++	No	++	++++	+++	++++
ICP-MS	++++	++++	Yes	++++	++++	++++	++++

Key: Low = +; High = ++++; UV-VIS = ultraviolet-visible spectrophotometry; IA = immunoassay; GC = gas chromatography; TLC = thin-layer chromatography; HPLC = high performance liquid chromatography; GC/MS = gas chromatography mass spectrometry; AAS = atomic absorption spectrometry; ICP-MS = inductively coupled plasma mass spectrometry.

From Dolgin, J., Human Clinical Toxicology, in *CRC Handbook of Toxicology*, Derelanko, M.J. and Hollinger, M.A., Eds., CRC Press, Boca Raton, FL, 1995, 697.

samples. The detection and measurement of toxicologically relevant concentrations of potent new drugs requires the use of analytical techniques on the forefront of instrumental technology.⁵⁻⁹

Immunoassay technology, now a mainstay of drug screening protocols, first became commercially available only about 25 years ago.¹⁰⁻¹⁴ At that time, classical thin-layer chromatography (TLC),¹⁵⁻²³ packed column gas chromatography,^{24,25} strip chart recorders, and ultraviolet-visible spectrophotometry were the state of the art in toxicology laboratories.²⁶⁻²⁹ Over the intervening years, capillary column gas chromatography,³⁰⁻⁴⁴ solid-phase extraction technology,⁴⁶⁻⁵³ nitrogen-phosphorus gas chromatography detectors,^{42,43,54,55} high-performance liquid chromatography (HPLC),⁵⁶⁻⁷⁴ ion trap mass spectrometry,⁷⁵⁻⁷⁹ and computerized mass spectrometry have become essential to the practice of post-mortem toxicology.^{80,99}

New technology is continually being introduced. Mass spectrometry is evolving to tandem mass spectrometry, and is being interfaced to liquid chromatographs.^{92,100-106} Chemical ionization, in both positive and negative ion modes, is increasingly used in the mass spectral analysis of drugs and poisons.¹⁰⁷⁻¹¹⁹ Robotic technology is used to increase efficiency of sample processing while maintaining and documenting sample integrity.¹²⁰⁻¹²³ At the same time, the proliferation of ever more powerful microcomputers, and sophisticated software applications, has vastly improved the processing and archiving of analytical data, control of instruments, laboratory management, and quality assurance monitoring.

While newer technologies have replaced many of the older, less sensitive, and less specific testing methods, some of the older tests, such as the microchemical tests, still have a place in the modern toxicology laboratory. But change is occurring so rapidly that today's technology may soon be obsolete. The best and most current guides to the innovations in testing methodologies are to be found in the scientific journals such as the *Journal of Forensic Science* and the *Journal of Analytical Toxicology*; the annual meetings of professional organizations such as the Society of Forensic Toxicologists and the American Academy of Forensic Sciences; and the annual meeting of the Pittsburgh Conference on Analytical Chemistry and Applied Spectroscopy. Table 12.3.1 compares the analytical techniques with respect to specificity, sensitivity, labor, cost, and applicability.

12.3.2 Simple Chemical Tests

Chemical tests were once the mainstay of post-mortem toxicology.^{21,124-127} Today, many have been abandoned and replaced by automated broad range screening procedures. However, some are

still useful as supplemental tests to rapidly and easily detect drugs and poisons that are not detected by the other screening tests.

Virtually all clinical and forensic toxicology laboratories utilize micro-color tests to indicate the possible presence of drugs or toxins; the so-called spot tests.^{21,125,127–133} Micro-color tests are performed by adding a single or multiple reagents to a specimen or extract and observing the color produced. Color tests are specific examples of the more general method of qualitative organic chemistry, relying on functional group reactions with the reagents. These tests require some expertise and familiarity to use, but are inexpensive and relatively rapid. They are nonspecific. However, in conjunction with other confirmatory tests, they can be used as rapid diagnostic aids.

Color tests can be combined with visible or spectrophotometric methodologies for qualitative to semiquantitative answers. Drugs including phenothiazines, salicylates, acetaminophen, carbamates, ethchlorvynol, and imipramine may be detected by colorimetric methods. Positive test results are confirmed and quantified by another technique. The greatest advantage of color tests is their ease of use. They can be performed directly on urine or a protein-free filtrate of blood or tissues. A negative color test precludes the need for any further work on that drug, assuming the detection limit of the test is acceptable. For example, the color test for phenothiazines is useful if an overdose has occurred, but is not sensitive enough to test for patient compliance with the drug.

12.3.2.1 Useful Color Tests

Some or all of the following tests may be incorporated in a routine screening protocol or some may be reserved for cases requiring more comprehensive poison screening.

Trinder's Reagent

Trinder's test is a simple color test that detects salicylic acid in urine or serum. It does not detect acetylsalicylic acid in gastric contents without prior hydrolysis by boiling with dilute HCl. Trinder's reagent is a mixture of ferric nitrate and mercuric chloride in dilute hydrochloric acid. It immediately produces a violet color when mixed with an equal volume of sample containing salicylate. Phenothiazines also give a positive reaction.^{125,126,129,133,134}

Fujiwara Test for Trichloro Compounds

A mixture of 1 mL 20% sodium hydroxide and 1 mL of pyridine at 100°C yields a red or pink color with chloral hydrate or other compounds with at least two halogens bound to one carbon.^{124–126,131,135} Trichloroethanol gives a yellow color. Contamination of the laboratory atmosphere with chlorinated solvents will give "false" positive results. Metabolites of carbon tetrachloride may also give a positive result with this test, but carbon tetrachloride is only partially metabolized to trichloromethyl compounds and the test may fail to detect this agent. A blank sample and a control (trichloroacetic acid) should be tested at the same time, with both blank and control solutions treated in similar fashion to the sample.

Diphenylamine Test for Oxidizing Agents

A solution of 0.5% diphenylamine in 60% sulfuric acid added to the sample or sample filtrate in a porcelain spot plate or a test tube immediately gives an intense blue color if an oxidizing agent is present. This test detects hypochlorite, chlorate, bromate, iodate, chromate, dichromate, nitrate, nitrite, permanganate, vanadate, lead (IV), or manganese (III, IV, or VII).^{125,126}

Ethchlorvynol (Placidyl) Test

In this test 1 mL of sample (urine or sample filtrate) is mixed with the reagent and allowed to stand for 20 min. If ethchlorvynol is present, the solution turns red or pink. The reagent consists of 1 g diphenylamine dissolved in 50 mL concentrated sulfuric acid and added slowly with stirring to 100 mL of 50% (V/V) acetic acid. The test is sufficiently sensitive to detect therapeutic concentrations.^{125,126,136}

12.3.2.2 Other Color Tests That May Be Included in a Screen

Other color tests that may be included in a screen can be found in various toxicology references.^{124–128}

12.3.3 Reinsch Test for Heavy Metals

A spiral of copper wire is first cleaned with 35% nitric acid and washed. It is then immersed in 15 mL of sample, acidified with concentrated HCl (4 mL), heated for 1 h, and then examined. A silver colored deposit on the copper indicates mercury, while a dark colored or black deposit is produced by arsenic, antimony, bismuth, tellurium, selenium, and sulfur. Further differentiation can be made on the basis of color of the deposit, and its solubility characteristics in potassium cyanide solution.^{128,137–141}

12.3.4 Microdiffusion Tests

12.3.4.1 Cyanide Test

In this test 2 mL of sample are placed in a screw cap culture tube. Disks are punched from a strip of Cyantesmo paper, available from Gallard-Schlessinger Chemical Mfg. Co. (Carle Place, New York), and one disk is stuck to the adhesive in the center of a 1-cm square of cellophane tape. The sample is acidified with H₂SO₄, the tape is placed over the mouth of the tube, with the adhesive and disk side down, and the tube is tightly capped. After 4 h at 35°C, the caps are removed and the color of the disk is compared with cyanide standards treated the same way. A pale green or yellow color is a negative result. Cyanide turns the disk blue in proportion to the concentration in the sample. Comparison of the color with standards from 0.2 to 5.0 mg/L cyanide can be used to estimate the concentration.

12.3.4.2 Carbon Monoxide

A simple test for carbon monoxide utilizes a procedure similar to the cyanide test described above, but using a disk of filter paper saturated with palladium chloride solution (1%) in 0.12 N HCl and dried. Carbon monoxide is released from hemoglobin by the addition of a solution containing lactic acid and potassium ferricyanide. Lead acetate is added to trap sulfide, which might interfere with the test. If carbon monoxide is present, the disk turns gray to black. While this test is simple, a faster and more effective method is to analyze the blood with a CO-Oximeter (Instrumentation Laboratories), which gives a result in % saturation of hemoglobin.

12.3.5 Other Simple Tests

12.3.5.1 Glucose, Ketones, Protein, and pH via a Diagnostic Reagent Strip (Dip-Stick)

Dip a strip briefly into the urine and read after 10 to 60 s. Elevated glucose may indicate diabetes. A positive result for ketones may indicate intoxication by acetone or isopropyl alcohol. This test may also be positive in starvation or in diabetic ketosis.

12.3.5.2 *Odor, Color, and pH of Gastric Contents*

Characteristic smells may indicate the presence of substances such as camphor, cresol, cyanide, ethanol and other organic solvents, ethchlorvynol, methyl salicylate, and paraldehyde. A high pH may indicate ingestion of alkali. A green or blue color suggests the presence of iron salts. Other colors may result from dissolution of colored pills or capsules. Intact tablets or capsules should be retrieved and examined separately.

12.3.6 Immunoassays

Immunoassays for post-mortem toxicology are sold commercially as kits. Often, they are exactly the same products as those used for urine drug screening in forensic urine drug testing programs.¹⁴² Such products are standardized and validated by the manufacturer, and are approved by the U.S. Food and Drug Administration (FDA). They are intended and approved for the analysis of particular specimen types, such as urine or serum. When urine cannot be obtained, other tissue may be used. A number of publications have described effective techniques for precipitating/extracting drugs from blood or tissue homogenates. Generally, the technique involves use of a solvent, such as acetone or acetonitrile, followed by evaporation of the solvent/water mixture and reconstitution in a suitable reagent for assay, according to the procedure for urine. However, application to specimens other than urine requires validation^{143–156}

Immunoassays are based upon the principle that antibodies can be produced that recognize and bind to specific chemicals by interacting with unique structural features of their molecules. The interaction is analogous to that of a lock and key. Some antibodies are so selective that they bind to only one substance, such as methamphetamine. Others interact with a variety of compounds with similar structures, such as amphetamine, methamphetamine, phentermine, ephedrine, pseudoephedrine, and others, though not with structurally dissimilar compounds such as morphine. For post-mortem screening, assays utilizing antibodies with broad selectivity for drugs within a particular class, such as sympathomimetic amines, are preferred over those with antibodies sensitive to one specific drug such as methamphetamine. Thus, a negative class selective assay can exclude all drugs with which it interacts, albeit with differing sensitivity for individual drugs. Conversely, a positive result requires further testing to distinguish among the possibilities. With few exceptions, all cross-reacting substances are of potential interest to the post-mortem toxicology laboratory.

Immunoassays used for drug screening utilize a competitive interaction between the drug in the specimen and a labeled drug in the reagent, for sites on an antibody specific to the drug being tested. The drug is detected by its ability to displace or block binding of a fixed amount of chemically labeled drug molecules that are included in the reagent. The label can be an enzyme, a fluorescent molecule, a radioactive isotope, or some other substance that can be detected by instrumental means. The object of the assay is to measure either the amount of antibody-bound or the amount of free labeled drug, which is related to the concentration of the targeted drug in the sample.

Some assays can distinguish between bound and free labeled drug in a mixture and are referred to as homogeneous immunoassays. Others require physical separation of bound and free label prior to making the measurement. These are called heterogeneous immunoassays. In general, homogeneous immunoassays are more readily automated and, thus, less labor intensive than heterogeneous immunoassays.

Various types of immunoassays use different detection principles, such as enzyme immunoassay (EIA), fluorescence polarization immunoassay (FPIA), radioimmunoassay (RIA), kinetic interaction of microparticulates in solution (KIMS), and enzyme-linked immunosorbent assay (ELISA). Each type has advantages and disadvantages in terms of cost, throughput, and time for analysis in post-mortem drug screening. The detection limit for various members of a class of drugs (e.g., opiates) or the degree of cross-reactivity for similar drugs (e.g., sympathomimetic amines) varies.

Each manufacturer of immunoassay reagents should be consulted for specific information regarding detection limits for various drugs within a class.

These assays are easy to perform, the results are “semiquantitative” (higher or lower than a predetermined calibrator cutoff concentration) rather than subjective (e.g., TLC), and they generally have low detection limits (0.02 to 1.0 µg/mL). Several non-isotopic immunoassays (e.g., EMIT™, CEDIA®, and FPIA) have been automated for post-mortem drug screening. Immunoassays complement chromatographic procedures (TLC and gas chromatography, GC) because they detect those drugs that would require hydrolysis prior to chromatography (e.g., morphine-3-glucuronide and oxazepam glucuronide), that may require a separate extraction (e.g., benzoylecgonine) or derivatization, or that have high TLC detection limits (e.g., phencyclidine). For abused drugs, immunoassays are the methods of choice for initial screening.

12.3.6.1 Enzyme Immunoassay

General

EIA reagents are available from several manufacturers. Spectrophotometric readings are used to measure the quantity of product produced by an enzyme-catalyzed reaction. The homogeneous EIAs are readily adaptable to automated clinical analyzers for rapid throughput of sample batches with minimal labor. Most are designed for screening urine samples, but they can be adapted for screening unhemolyzed serum or plasma. However, results depend on transmission of light through the reaction mixture, so these assays cannot be applied to turbid, highly colored, or opaque specimens, without first doing labor-intensive pre-extraction steps. The homogeneous EIA reagents are the most economical immunoassays for analysis of urine and stomach contents, although the extra labor required for their application to whole blood and other tissues may offset the reagent savings for those applications.^{10–14,142,157–166}

CEDIA

CEDIA assays represent state-of-the-art technique, utilizing two genetically engineered enzymatically inactive fragments of beta-galactosidase as the basis for a homogeneous enzyme immunoassay.^{167–173} Two separate genes are engineered to express two separate inactive polypeptide fragments: enzyme-donor (ED) and enzyme-acceptor (EA). These fragments can spontaneously recombine to form active beta-galactosidase enzyme. Ligands can be attached to the ED peptide in such a way that the degree of recombination is controlled by the binding of anti-ligand antibodies to the ED–ligand conjugate. CEDIA methodology is based on the competition between ligand in the sample and ED–ligand conjugate for a limited amount of antibody binding sites. The advantages of the CEDIA immunoassay system over conventional homogeneous EIAs include a linear calibration curve with high precision over the entire assay range, and lower limits of detection of analytes in human body fluids. Assay procedures can easily be automated and can be performed on most automated clinical chemistry analyzers.

ELISA

ELISA assays are heterogeneous enzyme immunoassays conducted in special multiwell (typically 96 wells) assay plates.^{174–179} They are more labor intensive than the homogeneous EIAs if assayed manually, although robotic equipment is available to process plates in a semiautomated manner. They require specialized plate readers to measure the reaction products. Costs are somewhat higher than homogeneous EIA reagents; however, ELISA assays are manufactured for some drugs for which no other immunoassay is commercially available (e.g., haloperidol, methylphenidate,

phenylbutazone, furosemide, phenothiazine, reserpine, and others). ELISA has the great advantage that it can be used with whole blood, typically diluted with water or buffer, and with proper validation even tissue homogenates.

12.3.6.2 Fluorescence Polarization Immunoassay

FPIA reagents were developed by Abbott Laboratories, and some are also available from Sigma Chemical Company.^{99,149,161–164,166,180–194} They are homogeneous immunoassays that can be used only in specialized instruments that are capable of exciting the fluorescein label with polarized ultraviolet light, and then measuring the intensity of polarized fluorescent emissions. Because the sample is highly dilute in the reaction mixture and the instrument measures emitted, rather than transmitted, light, FPIA is less subject to interference by color or turbidity of the sample matrix than are EIAs.

Most hemolyzed or whole blood samples, as well as serum, plasma, and urine, can be analyzed directly without extraction. If the sample is too dark to be analyzed without pretreatment, it can usually be analyzed after diluting with buffer, although with less sensitivity. In addition to their application to drug screening, some of the FPIA assays can yield quantitative measurements, because of the high specificity of their antibodies. The major drawbacks of FPIAs are the high price of reagents and the limited sample capacity of the instruments. The latter problem is being addressed with the introduction of a new high-capacity instrument (Abbott AxSYMTM).

12.3.6.3 Radioimmunoassay

RIA reagents are available from several manufacturers. They are heterogeneous immunoassays and, as such, are not readily automated. However, some RIAs have the antibody bound to the inside of the assay tube, which simplifies the separation and wash procedures. Most RIA reagents that are used in toxicology have ¹²⁵I as the label, and require a gamma counter to measure either bound or unbound label. Reagents are available for many drugs and drug classes, cost is reasonable, and sensitivity is excellent. The major drawbacks of RIA relate to the use of radioactive materials, i.e., the need for radioactive materials licensure and radioactive waste disposal, and the relatively short shelf life of the reagents.^{79,145,150–152,161,162,165,174,182,195–202}

12.3.6.4 Kinetic Interaction of Microparticles in Solution

KIMS (OnLine) reagents are available only from Roche Diagnostics. They are homogeneous assays with microscopic particles as the label. In the absence of drug, the labeled drug is bound by antibody, forming light-scattering aggregates. The intensity of light transmitted through the sample is measured spectrophotometrically in an automated clinical analyzer. Light transmission increases with concentration of unlabeled drug in the sample. Reagents are stable and sensitivity is good, although price remains somewhat higher than the EIA reagents.^{161,165,166,203–205}

12.3.6.5 Useful Immunoassays for Post-Mortem Toxicology Screening

Amphetamines (Class)

Polyclonal immunoassays for sympathomimetic amines including amphetamine, methamphetamine, phenylpropanolamine, ephedrine, pseudoephedrine, methylenedioxymethamphetamine (MDMA), phentermine, and related compounds are preferred over monoclonal assays for post-mortem toxicology. Approximate detection times are 12 h to 3 days. Administrative detection cutoffs are 300 to 1000 ng/mL in urine based on amphetamines or methamphetamine. They may be less sensitive for other drugs within the class.^{13,144,167,187,194,203,206–217}

Barbiturates (Class)

Most assays detect pentobarbital, secobarbital, amobarbital, butalbital, phenobarbital, thiopental, and related compounds. Normal detection times are 6 h to 2 days after administration. Detection cutoffs are 300 to 8000 ng/mL in urine depending on cross-reactivity.^{145,196,218–221}

Benzodiazepines (Class)

Most benzodiazepine immunoassays use antibodies directed to oxazepam. Their cross-reactivity for other benzodiazepines varies considerably, but most detect diazepam, oxazepam, flurazepam metabolites, chlordiazepoxide metabolites, alprazolam, triazolam, and related compounds. Lorazepam, flunitrazepam metabolites, and some others may not be detected by some immunoassays. Normal detection times are 3 h to 2 weeks. Administrative detection cutoffs are 300 to 3000 ng/mL in urine.^{144,146,173,176,181,188,191,192,222–234}

Benzoyllecgonine

The cocaine metabolite assays are designed to detect benzoyllecgonine, the principal urinary metabolite of cocaine. Cocaine and ecgonine methyl ester may also be detected if present in sufficient concentrations. Normal detection times are 6 h to 5 days. Administrative detection cutoffs are 300 ng/mL in urine.^{149,178,179,235–250}

Opiates (Class)

These assays detect a variety of opiates including morphine, morphine-glucuronide, hydromorphone, codeine, hydrocodone, and heroin metabolites. High concentrations of meperidine and oxycodone may give positive test results. Normal detection times are 6 h to 3 days. Administrative detection cutoffs are 300 to 3000 ng/mL in urine.^{12,144,154–156,160,165,167,173,202,204,215,245,251–257}

Phencyclidine

The phencyclidine (PCP) assays detect only PCP metabolites. Normal detection times are 24 h. Administrative detection cutoffs are 25 ng/mL in urine.^{156,173,221–265}

Propoxyphene

The propoxyphene assays detect the parent drug and the metabolite norpropoxyphene. In abuse situations, methadone (a close structural similarity) and chlorpromazine can produce a false positive. Normal detection time is 24 h. The administrative detection cutoff is 300 ng/mL in urine.^{156,226}

Cannabinoids

The cannabinoid assays interact with at least ten of the non-active metabolites of tetrahydrocannabinol (THC). Normal detection times range from hours to weeks, depending on the frequency, potency, dose, and route of administration. Administrative detection cutoffs for the principal urinary metabolites are 20 to 100 ng/mL in urine, depending on the assay.^{61,79,148,155,160,161,165,167,205,267–277}

Cyclic Antidepressants (Class)

The immunoassay for tricyclic antidepressants detects amitriptyline, nortriptyline, imipramine, desipramine, and their hydroxy metabolites, clomipramine, doxepin, protriptyline, cyclobenzaprine, and certain phenothiazines. Administrative detection cutoffs are 300 to 2000 ng/mL in urine.^{278–283}

12.3.7 Chromatography

Chromatographic drug screening techniques separate components of mixtures by partitioning them between a stationary phase, usually a solid or viscous liquid, and a mobile phase consisting of a gas or liquid. Under a given set of chromatographic conditions, the time required for a substance to traverse the chromatographic column (retention time) or the distance traveled on a TLC plate relative to the solvent front (R_f) is a constant. Separated analytes are detected and identified by a variety of techniques, and often quantitative measurements or semiquantitative estimates of analyte concentration may be made by reference to a standard curve. Chromatographic techniques that are currently used for screening purposes in post-mortem toxicology include TLC, GC, and HPLC.

12.3.7.1 Thin-Layer Chromatography

TLC is a versatile procedure that requires no instrumentation and thus is relatively simple and inexpensive to perform.^{16–21,23,82,284–293} However, its application to drug screening requires considerable skill to recognize drug and metabolite patterns and the various detection color hues. TLC techniques employ silica gel or a chemically modified silica gel as the stationary phase. The mobile phase consists of a mixture of organic solvents, often with a small quantity of acid or base to convert acidic or basic drugs to nonionic species. After extraction and specimen spotting, the TLC plates are developed with appropriate solvents to achieve chromatographic resolution. After the chromatogram is developed, drug spots are visualized by chemical modification to colored products or by absorption or fluorescence in ultraviolet light. Drug identifications are based on R_f values, color reactions, and presence of expected metabolite patterns. Standards are included on each plate to compensate for variations in R_f values.

With TLC, a large number of drugs may be detected, and presumptively identified, with a single analysis. TLC may be used to analyze serum, gastric contents, or urine. Urine, however, is the specimen of choice, since most drugs and drug metabolites are present in urine in relatively high concentrations. Although the detection limit varies for each drug, and with the conditions of extraction and detection, it is generally on the order of 0.5 to 4.0 $\mu\text{g/mL}$. TLC is less sensitive than immunoassay techniques, but its use is not restricted to the detection of only the drug or drugs for which antibodies are available. Literally hundreds of drugs can be detected and identified.

TLC can be used as either a screening or a confirmation procedure in toxicology tests. Many laboratories use TLC as a first screening step, because a wide variety of drugs/toxins can potentially be detected and presumptively identified. When used to screen, confirmation of TLC results can be made by using a variety of other procedures, including GC, GC/mass spectrometry (GC/MS), immunoassay, and HPLC. In some situations, the spot can be scraped from the TLC plate, extracted from the solid phase and injected directly into a GC or GC/MS for confirmation.

TLC will usually produce a spot for any organic drug/toxin that is present in sufficient concentration in urine or other body fluid. The major disadvantage of this technique is its insensitivity. In addition, when urine is the extracted specimen, drug metabolites are often present, and evaluation of a chromatogram containing several drugs and their metabolites can be complicated. However, the presence of known metabolites, when interpreted properly, adds support to the identification of the parent drug. TLC also has the drawback of being subjective in interpretation. A color-blind technologist will have difficulty interpreting the results.

Toxi-Lab® TLC

Over the last 20 years, classical TLC has been largely replaced in the post-mortem toxicology laboratory by the Toxi-Lab® TLC system.^{284,290–293} The Toxi-Lab system is a group of products produced by the AnaSys Corporation and marketed through major vendors of laboratory supplies and equipment. The Toxi-Lab TLC plates, Toxi-Grams®, are composed of glass fiber paper impreg-

nated with silica gel or a C-8 (8 carbon aliphatic) reversed-phase sorbent. Drugs are extracted from urine, stomach contents, or other specimens in prepared Toxi-Tubes® containing buffer and an optimized extraction solvent mixture. Sample extracts are evaporated in disposable aluminum cups with small disks of the same material as the plates. As the evaporation proceeds, extracted drugs are adsorbed into the disk, which, when dry, is inserted into a matching hole at the bottom of the plate. Standards are contained in similar disks. Both prestandardized and unstandardized plates are available and standard impregnated disks are available separately.

The prepared plate is developed in a glass chamber with a solvent mixture designated by the manufacturer for each chromatography system. After developing, plates are dried, and then drugs are visualized by sequentially dipping the chromatogram into a series of tanks containing reagents and viewing under long-wave ultraviolet (UV) light. Colors and positions of spots are recorded at each visualization stage. Photographic illustrations of visualization stages and metabolite patterns are available in a compendium comprising more than 100 drugs with new drugs added as data are developed.

An available PC-compatible search program can help with data analysis, yielding statistical probability for identifications. Systems are available to screen for basic and neutral drugs, acidic and neutral drugs, tetrahydrocannabinol metabolites, and opiates, as well as the C-8 reversed-phase system that is used for further differentiating and confirming presumptive findings. In addition, confirmatory procedures for many drugs are described. The Toxi-Lab system is a powerful tool for screening urine and stomach contents. It is less effective for blood and other tissues due to interference from lipids and sensitivity limitations.

12.3.7.2 Gas Chromatography

GC is widely used for qualitative and quantitative drug analysis. It is relatively rapid, and capable of resolving a broad spectrum of drugs. Modern gas chromatography employs fused silica capillary columns that are coated on their inner wall with a liquid stationary phase consisting of a polymer chemically bonded to the silica.^{45,80,294} The most common liquid phases are methyl silicones that contain 1, 5, or 50% phenyl side chains. The higher phenyl contents yield higher polarity liquid phases. Other polymers are used for special purposes.

The mobile phase is a gas, i.e., the carrier gas. Usually helium is used, although hydrogen, nitrogen, and gas mixtures may be preferred for some applications. The coiled column, which may be 10 to 60 m in length, is located in an oven having a precisely controlled programmable temperature capability. During a chromatographic analysis, the column temperature may be kept constant, raised at a selected constant rate, or programmed through a series of temperature ramps and isothermal intervals.

The separation capabilities of GC are determined by the polarity of the liquid phase, the flow rate and composition of the carrier gas, and the temperature program. Compounds are separated as a consequence of their different vapor pressures at the column temperature and their affinity for the liquid phase, which is related to their polarity.

In practice, the sample is injected manually or by an autosampler, either as an extract in a suitable organic solvent, or as a vapor of volatile analytes mixed with air or carrier gas. The sample is volatilized in the heated injection port and its constituents are swept into the column. As the analysis proceeds, some components move through the column faster than others, forming discrete bands that progress to the distal end and emerge into the detector, ideally in a pure state. GC detectors of various types recognize particular properties of substances, generating an electrical signal proportional to the quantity of the substance in the detector.

The resulting signal is electronically amplified and recorded on a moving chart or, more commonly, processed by a microcomputer to yield absolute and relative retention time, peak area, and height data for each detected component in the sample. Retention times of sample components, relative to a reference compound (internal standard) that is added to the sample, are constant for

a given set of chromatographic conditions. Presumptive identifications are based on relative retention times corresponding with those produced by standards under identical conditions. For drug screening, some laboratories use dual column GCs with both columns originating at the same injection port. The sample is divided between the two columns and analyzed simultaneously on both. Agreement of relative retention times in two columns of differing polarities provides greater certainty of identification.

Some drugs do not chromatograph well with GC because they contain polar functional groups that adhere strongly to the liquid phase or depress the vapor pressure. Such problems can often be overcome by converting the active functional groups to less polar derivatives; such as esters from alcohols, phenols, or carboxylic acids, or amides from amines. Derivatives may be selected to give longer or shorter retention times while improving peak shape and sensitivity.^{36,77,88,89,117,295–304}

Several types of detectors are used in post-mortem toxicology laboratories. Each has characteristics that allow for detection and quantification of some, but not all, of the drugs and poisons that are of concern to the post-mortem toxicologist.

Flame Ionization Detector

The flame ionization detector (FID) uses a hydrogen/air flame to oxidize sample components that emerge from the column. Substances containing carbon yield a charged plasma. Electrodes produce a high-voltage field that deflects the charged particles to a collector that produces an electric current with a magnitude proportional to the quantity of the component. The FID detects virtually all drugs that can be passed through the GC; however, lipids and other matrix-derived components interfere with the detection of drugs and limit practical sensitivity.

The FID, once the mainstay of GC in toxicology laboratories, is still used for the analysis of alcohols and other volatile substances in the GC equipped with an automated headspace sampler. Barbiturates and other acidic and neutral drugs are detected and quantified effectively with FID.^{305–310} However, most GC basic drug screens typically employ nitrogen/phosphorus detectors (NPD), which provide better sensitivity and selectivity than FID.

Nitrogen/Phosphorus Detector

The NPD has some similarities to the flame ionization detector in that a hydrogen-air flame is used, but the collector is a ceramic bead coated with a rubidium salt. The NPD is insensitive to carbon when properly adjusted, but it responds with high sensitivity to compounds containing nitrogen or phosphorus. Furthermore, it can be tuned to maximize sensitivity to either element. The selectivity for nitrogen makes the NP detector ideal for screening basic drugs, which all contain amine functions.^{30,42,43,55,311–314} Lipids and other non-nitrogenous matrix components do not interfere with the analysis.

Electron Capture Detector

The electron capture detector (ECD) contains a radioactive nickel-63 foil that emits high energy electrons (beta particles). The carrier gas is ionized by the radiation, forming anions that establish an ion current between two electrodes. Sample compounds, emerging from the GC column, extract electrons from the ionized gas, decreasing the current flow. The change in current is the signal produced by the detector.

Most substances do not capture electrons and are not detected by the ECD. However, the presence of two or more halogen atoms or a nitro or nitroso group in the molecule allows the substance to be detected. The outstanding sensitivity of the ECD for most polyhalogenated compounds is the reason for its use in the analysis of benzodiazepines.^{232,315–317} A laboratory possessing

a GC with ECD detector must have a radioactive materials license. A general license is sufficient for sealed detectors, but a specific license is required if the detector can be disassembled.

12.3.7.3 Gas Chromatography/Mass Spectrometry

GC/MS is a powerful analytical tool for identification of semivolatile organic compounds. It combines the separation efficiency of gas chromatography with the structure elucidating capabilities of mass spectrometry.^{6,78–83,94,97,98,318–321} When it is used to identify unknown substances in a sample extract, the instrument may be programmed to automatically search for matches against a predefined library (target compound analysis) or it can acquire spectral data for later analysis. In the latter instance, the operator examines a chromatogram peak by peak, extracting background-subtracted spectra and searching spectral libraries by using a pattern-matching algorithm through the instrument's data system. If no acceptable match is found, the spectrum can be visually compared with printed compilations of mass spectral data. Considerable experience is required for effective and efficient substance identification by GC/MS. A chromatogram may consist of hundreds of peaks, most of which represent endogenous compounds. Recognition of frequently encountered patterns can save considerable time by avoiding unnecessary library searches. Conversely, the experienced operator will recognize the novel pattern as one that requires investigation. Nevertheless, a thorough search of a GC/MS data file can take an hour or more.

The price of GC/MS instrumentation has dropped to the point where many laboratories use it as a primary drug screening technique. However, some laboratories still rely on less definitive techniques such as TLC, GC, or class selective immunoassays for pre-screening.^{80,255,256,269,297,319,322–324} When GC/MS is employed to identify unknown peaks from a GC analysis, the portion of the chromatogram that must be examined can be narrowed if the same type of column and same column temperature program are used in both instruments. The remaining extract from the GC analysis can be injected into the GC/MS. Knowing the relative retention time of the unknown, the operator can first locate the peak corresponding to the internal standard and then estimate the region of the GC/MS chromatogram where the unknown peak should be. That region is examined carefully to locate and identify a peak whose spectrum is inconsistent with expected endogenous compounds. With some instrumentation it is possible to simultaneously inject extracts onto a system with both MS and NP detector systems. This may be done either by connecting two columns to a single injector or by splitting the effluent from one column into two detectors (one MS, one NP).

In the identification of substances giving rise to unknown spots on TLC, an extract of the sample is analyzed in the GC/MS with a column temperature program extending from below the boiling point of the solvent to 300°C or higher. When the GC/MS run is complete, the entire chromatogram is examined. Time can be saved by initially examining the 20 or 30 largest peaks first. The GC/MS is much more sensitive than TLC, so any component that gives a visible spot should produce a large peak on the GC/MS. Alternatively, the operator may examine all peaks, and detect even substances missed by the TLC analysis. In most cases, such sensitivity is unnecessary for analyzing urine or gastric contents, but it can be useful when potent drugs such as fentanyl or haloperidol must be excluded.

An alternative approach to the identification of unknowns detected by TLC is to scrape the spot from a duplicate plate and analyze it by GC/MS. In practice, a second TLC plate is prepared and developed, but is not sprayed or dipped with color reagents. Instead, the area of the plate corresponding to the unknown spot is scraped (or cut from a Toxi-Gram), and the drug is eluted into a solvent. The solvent is evaporated, and the residue is redissolved and analyzed by GC/MS. This procedure should produce a single major peak on the GC/MS that corresponds to the unknown spot on the TLC plate. The spectrum of the major peak can then be searched to identify the unknown.

GC/MS is often used to identify the drug, or drugs, giving rise to a positive result in a class selective immunoassay test. Such analyses are most efficiently accomplished by methods that search an area of the chromatogram for patterns matching reference spectra in a computer library.

The library is generated by analyzing a standard of each of the targeted drugs and storing a representative spectrum in the data system.^{92,199,256,325} The search can be programmed to take place automatically at the end of each data file acquisition. However, the data must be reviewed by the operator before reporting.

GC/MS data can be used for both identification and confirmation in drug screening.^{318,320,321,325–327} However, for it to serve as a final confirmation test, the GC/MS analysis should be performed on a separate aliquot or a different specimen from that which yields the initial presumptive finding.

12.3.7.4 High-Performance Liquid Chromatography

HPLC utilizes a column filled with microscopic particles of silica, or resin particles bonded with a polymer whose side chains have specific functional groups.^{57,59,64,69,328–332} The polymer is the stationary phase in HPLC, and the nature of the side chains determines the type of interactions the column will have with analytes. Various normal phases and reverse phases are available. Normal phases are characterized by polar side chains such as silica, diol, amino, and cyano, whereas reverse phases have nonpolar side chains such as 8 carbon (C-8) and 18 carbon (C-18) aliphatic and phenyl moieties. Anion and cation exchange phases are also available.

The mobile phase in HPLC is a mixed solvent containing a buffer to suppress or induce ionization of analytes as required for the intended separation. The solvent composition may be kept constant (isocratic) or the percentages of components may be varied (gradient) during the analysis. For instance, in reverse-phase HPLC, the mobile phase will start at higher polarity. As the run proceeds, the polarity is decreased, enabling the removal of any remaining nonpolar substances from the nonpolar reverse phase column, while decreasing the tendency toward broad peaks near the end of a run.

Ultraviolet Absorption Detectors

The most common detection systems for HPLC are UV absorption detectors.^{56,64,72,331,332} The less expensive detectors measure absorption at a single wavelength which may be fixed (e.g., at 254 or 280 nm) or variable over a range of 190 to over 340 nm. The variable wavelength detectors are set to a desired wavelength by the operator, and some can be programmed to change wavelengths during the analysis. However, the time required to change wavelengths precludes using variable wavelength detectors for spectral scanning of peaks.

Diode Array Detectors

Photo diode array detectors simultaneously measure absorbance at many small wavelength increments over a broad wavelength band.^{46,57,58,64,69,70,73,74,333–348} The detector uses a diffraction grating to break the light beam into a spectrum that is focused onto an array of UV-sensitive photo diodes. Thus, UV spectra of individual peaks can be recorded. A data processing system enables the instrument to determine peak purity by comparing spectra at the leading and tailing ends of a peak and to create and search libraries of target analyte spectra. The sensitivity of the diode array detector is poorer than that of the fixed or variable wavelength, but the availability of spectral data makes it a valuable tool for drug screening.

Fluorescence Detectors

Fluorescence detectors, with variable excitation and emission wavelengths, provide high sensitivity and specificity for the detection and quantification of fluorescent compounds, but they are more useful for quantification than for screening. Fluorescence detection could be used to provide

a sensitive screen to target a single substance or a group of substances with similar fluorescence characteristics and different retention times.^{56–59}

Advantages and Disadvantages of HPLC

HPLC systems can be equipped with autosamplers, manual injectors, or both. In general, the greatest screening efficiency is achieved through automation. Increased applications of HPLC for drug screening are likely. Substantially more definitive drug identification can be achieved by the use of a mass spectrometer as the HPLC detector. The relatively high cost of these liquid chromatograph/mass spectrometer-coupled instruments limits their current usage for general drug screening or confirmation, although their use is becoming increasingly more common.

HPLC is a more expensive and labor intensive and less sensitive analytical technique than GC, so it is less commonly used for screening. However, it can be used to detect many drugs and poisons that are thermolabile, too polar or lacking in sufficient volatility for analysis by GC. In addition to the qualitative information obtained from the chromatographic retention time, quantification can also be obtained. The signal generated by the detector is proportional to the amount of substance detected. Therefore, by preparing standards of known concentration and treating them in like fashion to the case specimen, the amount of toxin in the specimen can be quantified. The precision of the quantification can be enhanced by adding an internal standard at the beginning of the extraction. The internal standard is usually a compound with similar extraction and chromatographic characteristics to the analytes of interest. The presence of the internal standard permits the quantification to be based on the ratio of analyte to internal standard peak heights or areas. Because ratios are used instead of absolute amounts, the need for quantitative transfers in the extraction process is removed.

REMEDi HS™ HPLC

A commercial, completely automated HPLC system designed for drug screening is available (REMEDi HS; Bio-Rad Laboratories, Hercules, CA).^{349–352} This system utilizes four columns in series and column switching techniques to extract, separate, and perform a spectral scan on eluted drugs. Identification of about 500 drugs and metabolites is based on computer matching of retention time and spectra with comparable data stored in the drug library.

Quantification of identified drugs may also be performed. REMEDi HS was developed for the clinical laboratory, but it can be adapted for post-mortem drug screening. Urine, serum, and plasma can be analyzed directly, but whole blood and tissues require manual extraction prior to analysis. Sensitivity for many drugs is not as good as GC with NPD, but should be sufficient for screening urine or stomach contents. If REMEDi HS is applied to screening blood or tissues, sensitivity may not be adequate to detect therapeutic or intoxicating concentrations of some important drugs, but should be adequate for detecting lethal concentrations.

The REMEDi HS system can be complementary to other drug screening techniques, detecting drugs that would otherwise be overlooked and providing corroborative evidence to confirm identifications.

12.3.8 Ultraviolet-Visible Spectrophotometry

Ultraviolet-visible (UV-Vis) spectrophotometry was one of the earliest instrumental techniques used in post-mortem forensic toxicology.^{26–29} The use of ultraviolet and visible spectrophotometry as a screening tool is based on the fact that many drugs contain aromatic nuclei that absorb light in the UV and visible regions. Such drugs have absorption spectra with maxima and minima at characteristic wavelengths. Furthermore, the spectrum often changes with the ionization state of the drug in acidic or basic solutions. UV absorption maxima and entire spectra of drugs and poisons are available from various references.

Several limitations, however, affect the use of spectrophotometry. The major limitation is the lack of sensitivity required to detect many of today's therapeutic or misused drugs. Another drawback of spectrophotometry is the requirement that the drug be isolated in a form free from substances with overlapping spectra. Drug mixtures and impure extracts yield mixed spectra that may not be interpretable. In addition, spectrophotometry is not able to distinguish between the parent drug and metabolites. Some of a drug's metabolites may be active while others are inactive, and there is a need to distinguish between these compounds. In spite of these deficiencies, a role remains for spectrophotometric methods for some drug and toxicant analyses. UV spectrometry is especially useful for purity and concentration checks of primary and stock standards.

12.3.9 Spectroscopic Methods for Analysis of Toxic Metals and Metalloids

Toxicologists should be prepared to support investigations that involve toxic exposure to metals and metalloids. Proper sample collection and rigorous state-of-the-art analytical techniques are critical to prevent exogenous contamination.^{353,354} A number of different techniques may be employed for the identification of such compounds: flame atomic absorption spectroscopy (FAAS),³⁵⁵ graphite furnace atomic absorption spectroscopy (GF-AAS),^{356,357} inductively coupled plasma-emission spectroscopy (ICPAES),³⁵⁸ and inductively coupled plasma-mass spectrometry (ICP-MS)^{358,359} may all be used. These are sensitive and specific techniques that provide the laboratory with the capability to measure a broad range of metals. An in-depth discussion of methods used for metal analysis is beyond the scope of this chapter.

12.3.10 Sample Preparation

12.3.10.1 Extraction Methods

There are two approaches to the screening of biofluids for drugs or poisons. One is the direct analysis of the specimen for the presence of a specific analyte or its class, without isolation or purification. The other is isolation of the analyte from the sample followed by instrumental analysis of the concentrated extract. The most common example of this is liquid-liquid extraction of an appropriately buffered sample with an immiscible organic solvent.^{21,23,25,43,65,66,71,314,360–371} The proper choice of sample, pH, and solvent will effectively remove the target analytes from the aqueous sample matrix.^{21,25,362,371–373} Separation of an analyte from interfering substances usually will require more involved techniques.

Liquid–Liquid Extraction

The liquid–liquid extraction technique dates to the mid-19th century when Stas and Otto developed extraction schemes for nonvolatile organic compounds. The method utilizes differences in the pH and solubility characteristics of various analytes. A basic compound is in the non-ionized form in alkaline pH; an acidic compound is in the ionized form in a similar medium. A compound in its non-ionized form prefers the lipophilic environment of an organic solvent to the aqueous environment of the biologic sample. It is on this basis that the separation of drugs from the biologic matrix occurs. The specimen is buffered according to the pH characteristics of the analyte of interest and mixed with an immiscible organic solvent. Commonly used solvents are hexane, toluene, diethyl ether, chlorobutane, dichloromethane, chloroform, or mixtures of these. Ionized compounds and many of the biologic components such as proteins remain in the aqueous layer while the un-ionized drug molecules are transferred to the organic solvent.

The extraction process can be illustrated by taking as an example a basic drug of pK 8, present in plasma. If the plasma is brought to pH 10 using a suitable alkali or alkaline buffer and is shaken with a suitable organic solvent, the drug will be removed from the aqueous into the organic phase.

Unfortunately, many endogenous bases and neutral compounds will also be extracted if they are soluble in the organic solvent. The organic phase is then separated from the aqueous phase (using a Pasteur pipette, for example). This is usually done after centrifugation, to completely separate the two phases.

For drugs that behave like strong acids and bases, a further purification step called back-extraction can be carried out. By shaking the organic phase with dilute acid, such as 0.1 *N* sulfuric, the basic drug will now be ionized and will no longer be as soluble in the organic phase: it will be extracted into the aqueous phase. Any neutral compounds will be left behind in the organic phase. Endogenous bases may also be co-extracted with the basic drug, but by carefully choosing the pH and the organic solvent the amounts of these bases can be reduced. The acidic aqueous phase is then made alkaline by the addition of a base, such as 2 *N* sodium hydroxide, and shaken with fresh organic solvent to take the drug into the organic phase. The organic phase can be separated, evaporated, reconstituted, and analyzed.

In many methods the organic phase, containing the drug, is washed with water, and the washings are discarded. This step must be carefully controlled. For example, if the drug is a moderate to strong base and the wash water is even slightly acidic, then some of the drug may be removed into the aqueous phase. If such a process takes place, then low and very erratic recoveries will result.

Before leaving the subject of solvent extraction a number of simple points should be emphasized:

1. In general the least polar solvent capable of extracting the drug in question should be used in order to reduce the possibility of co-extracting endogenous materials. The least polar solvents are the hydrocarbons, such as hexane, toluene, chlorinated hydrocarbons, and diethyl and related ethers. Ethyl acetate is more polar, and the short-chain alcohols are very polar and miscible with water to a greater or lesser degree.
2. Many drugs are so highly lipid soluble that they can be extracted into nonpolar solvents, even in the ionized state. For example, the β -adrenoreceptor blocking drug propranolol has a pK of about 9.5, and therefore in a pH 7.4 buffer it is more than 99% ionized. Since its partition coefficient, between *n*-octanol and pH 7.4 buffer at 37°C, is 20.2, this means that the ionized drug is highly soluble in *n*-octanol.
3. Many extraction procedures employ a ratio of solvent to aqueous phase greater than unity in order to reduce the possibility of emulsion formation during extraction. The ideal is a 10:1 solvent-to-sample ratio. There are, however, successful methods that use ratios very much less than unity. Troublesome emulsions can also be avoided or reduced by saturating the aqueous phase with an inorganic salt, such as sodium chloride, before extraction.
4. Recoveries can be increased by using mixed solvents such as hexane: butanol (9:1) or hexane: isoamyl alcohol (97:3). Such solvents are also mandatory to efficiently extract polar drugs or metabolites.
5. Extraction conditions should always be optimized using the relevant biological fluid. It should not be assumed that the extractability from water will exactly match that from blood or tissue homogenates.
6. When extraction conditions have been optimized, it is worthwhile to put a series of specimens through the complete procedure, half of them diluted approximately tenfold. Although this does not always succeed, it can result in cleaner extracts.
7. The multiple step liquid-liquid extraction process is quite effective in separating analytes from biologic specimens, but is also time-consuming. In an attempt to alleviate this time-related problem, solid-phase extraction (SPE) techniques have been developed.

Solid Phase Extraction

In SPE, the specimen is applied to a solid packing material, which is usually, but not exclusively, silica gel based. The sample is partitioned between the matrix and the solid phase, which provides the separation. The general process of SPE involves several steps: (1) column conditioning,

(2) addition of specimen, (3) column washing with solvents to remove interfering substances, and (4) analyte elution.^{46–53,55,57,59,63,69,70,72,82,91,308,374–391} Each individual step depends on the analyte of interest, or the type of extraction column, and method development frequently involves a significant amount of trial and error. SPE is utilized in a vast number of analytical methods developed for drug analysis in human post-mortem materials.³⁹² The advantages of SPE procedures include decreased operator time, reduced solvent volumes, and increased extraction efficiency. In post-mortem toxicology, the availability of automated SPE systems has made this extraction technique attractive to forensic laboratories with a high throughput of post-mortem samples, where several extraction programs adjusted for different analytical methods can be run on the same system. For certain analyses, immunoaffinity SPE techniques may be employed, significantly improving the purity of the sample. This variant of the SPE technique has been used in the analysis of a large number of drugs.³⁹³

A little more than a decade ago, solid-phase microextraction (SPME) was introduced and the technique has since been extensively used in several areas, including analysis of drugs and endogenous compounds.^{394,395} SPME has many advantages over other extraction methods; it is simple, rapid, efficient, and requires no solvent. All steps of sample preparation, i.e., extraction, concentration, derivatization, and transfer to the chromatograph, are integrated in one step and in one device. In forensic toxicology applications of this technique include analytical methods for barbiturates,³⁹⁶ drug screening in hair,³⁹⁷ organophosphates,³⁹⁸ GHB,³⁹⁹ and certain pharmaceutical drugs.⁴⁰⁰ SPME is typically followed by GC/MS or LC/MS analysis, but may be combined with other methods. Recently, SPME has been applied in a methodological approach to determine the binding parameters of drugs to human serum albumin. From these parameters the concentrations of albumin, free drug, and total drug can be calculated in unknown mixtures.⁴⁰¹

A closely related technique is solid-phase dynamic extraction (SPDE), based on an inside needle capillary absorption trap. An automated HS-SPDE-GC-MS procedure was developed and applied for analysis of drugs of abuse in hair, and was found to provide, compared with SPME, a higher extraction rate, in addition to a faster automated operation and greater stability of the device.⁴⁰²

Summing up, the development of the several different modifications of solid-phase extraction techniques in recent years is impressive, and is comparable to the rapid innovations in LC/MS instrumentation. It seems likely that we will face a large number of new methodological concepts and applications of SPE techniques that will resolve several analytical problems in forensic toxicology.

pH Adjustment for Extraction

Weakly acidic drugs, such as barbiturates, primidone, and phenytoin, can be separated from the specimen by using a liquid–liquid or solid-phase extraction at pH 5. This extraction also removes some neutral drugs, such as meprobamate, glutethimide, and carbamazepine. After solvent concentration, these drugs can be identified by TLC, GC, or HPLC.

The largest group of drugs that are normally encountered in the post-mortem laboratory are the organic bases. These include antiarrhythmics, antidepressants, antihistamines, benzodiazepines, cocaine, narcotic analgesics, nicotine, phencyclidine, phenothiazines, and sympathomimetic amines. These drugs all extract under alkaline conditions.

Amphoteric drugs such as morphine and benzoylcegonine require careful adjustment of pH for their efficient extraction by liquid–liquid procedures. Amphoteric compounds contain both acidic and basic functional groups. If the aqueous phase is too acidic or too basic, one of the functional groups will be ionized, and extraction will be inefficient. The pH must be close to the isoelectric point for high recovery by liquid–liquid extraction. Such compounds may be isolated by solid phase techniques, if a column with ion exchange functions is used. The pH is adjusted to completely ionize one of the functional groups in the analyte. The appropriate solid phase will capture ionized analyte as the sample passes through. The sorbent is washed to remove impurities, and then the analyte is recovered in either an acidic or basic elution solvent in order to reverse its ionization.

12.3.10.2 Hydrolysis to Release Drugs in Sample Pretreatment

Before extraction, tissues may be homogenized with a blender or an ultrasonic disruptor, or they may be hydrolyzed by enzymes such as Subtilysin Carlsburg or Protease K to produce a homogeneous fluid sample.^{39,365,378,403} Conjugates can be cleaved by gentle but time-consuming enzymatic hydrolysis, or by rapid acid hydrolysis.^{34,53,117,224,227,404,405} However, the formation of artifacts during the latter procedure must be considered.

12.3.10.3 Applications

Universal liquid–liquid extraction procedures are preferable for general unknown analysis because substances with very different physicochemical properties must be isolated from heterogeneous matrices. On the other hand, solid-phase extraction is preferable if target compounds must be selectively isolated from relatively homogeneous samples, such as urine for confirmation of a single drug, or metabolite, or a group of drugs with similar extraction properties.

12.4 STRATEGIES FOR POST-MORTEM TOXICOLOGY INVESTIGATION

Edited and Revised by Henrik Druid, M.D., Ph.D.

Associate Professor, Department of Forensic Medicine, Karolinska Institute, Stockholm, Sweden

From the original by W. Lee Hearn, Ph.D.

Director, Dade County Medical Examiner Toxicology Laboratory, Miami, Florida

12.4.1 Screening Strategy

The first step in any case is to review the case history and autopsy findings. If the pathologist makes no specific requests for analysis, then responsibility for deciding which tests to do falls exclusively to the professional judgment of the toxicologist.¹⁻⁹

Obviously, cases of suspected drug intoxication require the most comprehensive testing, typically on samples of blood, liver, gastric contents, and urine or bile.^{10,11} Tests in the case of a drug-related homicide may include a blood-ethanol analysis, and a standard drug-of-abuse screen on urine, with the concentration of any identified drug being quantified in the blood.¹²⁻¹⁸ Fatalities involving motor vehicle drivers require a blood-ethanol determination, and a comprehensive urine screen with any positive drug concentration quantified in the blood.¹⁹⁻²³ Fatalities resulting from a fire require blood-carbon monoxide and sometimes cyanide analyses in addition to alcohol and other drugs.²⁴⁻²⁶

12.4.2 General Concepts

Screening protocols should include tests capable of detecting as many drugs as possible, within the constraints imposed by the available specimens, the laboratory's workload, and requirements specific to the case (Figure 12.4.1).^{5-9,27} Most laboratories lack the resources required to treat every case as a general unknown, applying test after test until all possible drugs and poisons are ruled out. Such an approach may occasionally be warranted when there is a high suspicion of poisoning, but usually several standardized protocols can be used to eliminate most of the substances that can realistically be expected in a sample.

A broad-spectrum screen, capable of detecting or eliminating most of the common drugs, usually requires a combination of three or more techniques.^{1,2,11,28-88} Additional tests can be combined with standardized screening protocols, thereby expanding the screening capability to encompass additional drugs of concern based upon the specifics of the case. Table 12.4.1 shows test panels commonly employed for screening various types of cases.

The most effective strategies employ a combination of immunoassays, with chromatographic techniques, and chemical tests, in order to detect a wide range of substances. Immunoassays are used to test for classes of drugs with similar structures, while the chromatographic tests detect large groups of drugs with similar extraction characteristics, polarities, and detection characteristics. Chemical tests are selective for the chemical reactivity of substances with similar structures. The type of analysis required also depends on the type of biologic specimen to be analyzed. A putrefied liver specimen, for example, will require greater sample preparation than would a fresh urine specimen. Some drugs are present in much smaller concentrations than others and thus require more sophisticated detection techniques.

It is impossible to design a single analytical scheme that is capable of detecting all the available drugs and poisons while being suitable for the wide variety of specimen combinations that may be submitted. In general, a collection of about a dozen standard general screening methods is supplemented with as many special methods as required. Because the main objective is qualitative

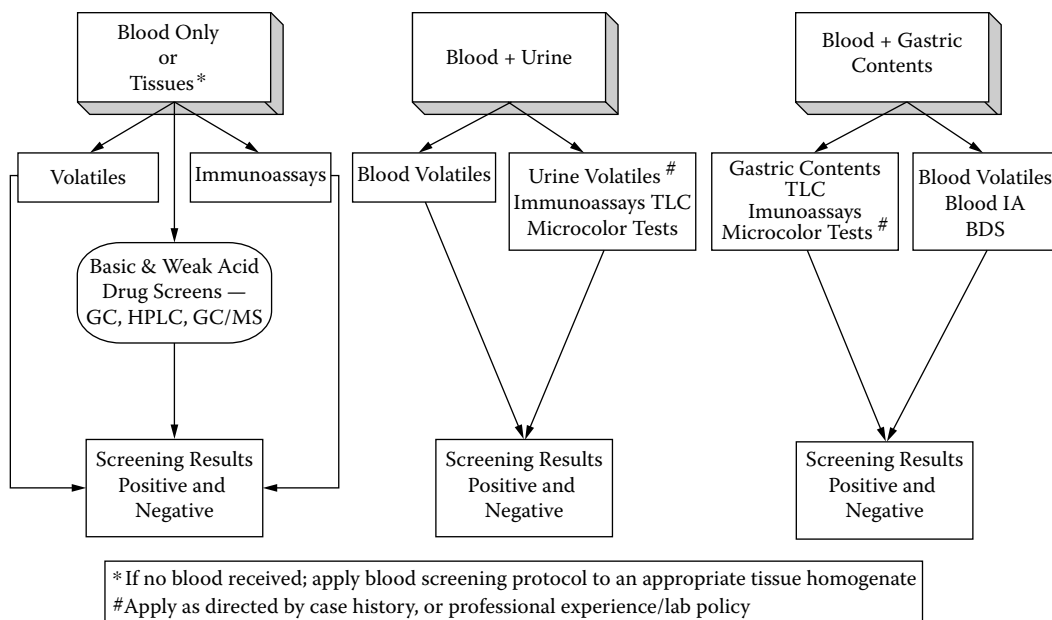

Figure 12.4.1 Post-mortem forensic toxicology screening protocols.

detection, rather than quantification, general screening methods are usually more flexible than special methods and can therefore be applied to a wider variety of materials. A good general method will provide a provisional identification, which can then be confirmed by the application of a quantitative directed analysis.

Often, the nature of a suspected toxin is unknown. The classic example is a person who has expired under suspicious circumstances and where the history, scene, and autopsy fail to disclose a definitive cause of death. In such cases, the screening strategy must be more extensive, since thousands of toxic drugs and chemicals are available on the market worldwide. A systematic procedure that allows the simultaneous detection of as many toxicants in biosamples as possible is necessary for a comprehensive toxicological analysis.^{1,2,4,5,89–91}

12.4.3 Basic Strategies

In laboratories with small caseloads, each case may be reviewed individually by the director who assigns specific tests. Testing large numbers of samples proceeds more efficiently, and in a more organized fashion, when standardized assay panels are performed on batches of samples. Blood and urine are the specimens of choice to screen for drugs and poisons. Depending on the circumstances of the case, other samples include liver, stomach contents, or bile.

The blood volatiles screen detects and quantifies ethanol while simultaneously screening for methanol, isopropanol, and acetone as well as other volatiles, such as halogenated and non-halogenated hydrocarbons that are sometimes inhaled for purposes of intoxication.^{46,70,92–95} Each of the immunoassay tests is used to detect substances that cannot easily be included in one or two chromatographic procedures, or for which routine chromatographic tests may be too insensitive, or where specialized extraction or derivatization conditions may be required.

12.4.3.1 Amphetamines

The amphetamines are relatively volatile, and can be lost by evaporation if the extract is not first acidified. In addition, they tend to give tailing peaks unless the gas chromatography (GC)

Table 12.4.1 Case Management by Manner of Death

Pending pathology	X	X				X		
Pending toxicology	X	X	X	X	X	X	X	As required

Immunoassays imply the use of urine, however, if a urine specimen is unavailable, or "indicates the presence of" a drug, a blood analysis should follow. At a minimum, perform amphetamines, barbiturates, benzodiazepines, cocaine, opiates, PCP, and others as required by case type and history.

CO (carbon monoxide): Between the months of September and May, request on all MEO (medical examiner office) cases involving apparent natural death and pending cases occurring indoors.

MCTs: Require urine and gastric contents.

Key: IA= immunoassays; B/U = blood and/or urine; CO/CN = carbon monoxide and cyanide; BDS = basic drug screen; WAN = weak acid neutral drug screen; TOXI-A/B = commercial thin-layer chromatography acids and bases; MCT = microcolor tests; MVA = motor vehicle accident; COD = cause of death; SIDS = sudden infant death syndrome; APAP = acetaminophen; ASA = salicylates.

columns are well maintained, or the amphetamines are derivatized. However, ToxiLab can effectively detect and differentiate the sympathomimetic amines in urine, so the amphetamines immunoassay could be omitted if ToxiLab is used. If an amphetamines immunoassay is used, it should be one of broad class selectivity, not one of the newer and more specific monoclonal antibody assays, so that it has the chance of detecting the maximum number of amphetamines and related drugs (e.g., ephedrine, pseudoephedrine).⁹⁶⁻⁹⁸

12.4.3.2 Barbiturates

An immunoassay for barbiturates can eliminate the need for labor-intensive chromatographic screens of weakly acidic and neutral drugs in the majority of cases. Only those cases testing positive, or where phenytoin is indicated, need the chromatographic screen. The ToxiLab B system can help to differentiate barbiturates in urine, or the testing can proceed directly to a GC, HPLC, or GC-MS screen on an acidic drug extract of blood to identify the specific barbiturate(s) present in the body.⁹⁹⁻¹⁰⁴

12.4.3.3 Benzodiazepines

The benzodiazepines comprise a large class of drugs that are often detected in post-mortem cases. ToxiLab does not ordinarily detect them in urine at therapeutic doses, and a basic drug GC screen rarely detects the more potent drugs in this class, except in cases of overdose. Available immunoassays can yield positive results in urine for metabolites from most of the common benzodiazepines. Exceptions are lorazepam and flunitrazepam. GC with electron capture detection, or GC/mass spectrometry (GC/MS), may be applied to urine or blood to differentiate benzodiazepines and to detect those that are missed by immunoassays.^{105–117} Whether or not to use these more labor intensive chromatographic tests in the absence of a positive immunoassay depends upon the potential significance of a benzodiazepine, if it were to be found, and on any indications from the investigation that one may have been taken. Several methods have also been published for the detection of a wide range of benzodiazepines by LC/MS or LC/MS/MS.

12.4.3.4 Cocaine

Cocaine should always be included in a post-mortem toxicology screen. Even infants and elderly individuals occasionally test positive. The most efficient way to screen for cocaine is to use an immunoassay for benzoylecgonine.^{118–121} Although both ToxiLab A and basic drug GC screens can actually detect cocaine itself, special procedures are required for the chromatographic detection of benzoylecgonine. Cocaine may not always be found in the urine with benzoylecgonine, although benzoylecgonine is almost always found whenever cocaine is present.

12.4.3.5 Opiates

The common opiates include morphine, 6-monoacetylmorphine, codeine, hydromorphone, hydrocodone, and oxycodone. Routine ToxiLab A or basic drug GC screens detect codeine, hydrocodone, and oxycodone. These methods are less effective for morphine and hydromorphone, which are usually found in the urine as water-soluble conjugates of glucuronic acid. Immunoassays can detect both parent drug and metabolites. Differentiation of opiates is usually accomplished by GC/MS, using procedures that include hydrolysis of conjugates and derivatization for maximum sensitivity and specificity, or by LC/MS.^{122–124}

12.4.3.6 Phencyclidine

Phencyclidine (PCP) is more commonly encountered in some regions, while not in others. It is a powerful dissociative anesthetic with significant effects on behavior at low doses, and should be included as part of the post-mortem drug screen. Both thin-layer chromatography (TLC) and GC detect PCP, although they may be insufficiently sensitive to reliably rule it out. Immunoassays capable of detecting PCP in urine down to 25 ng/mL provide a reliable screening test.^{125,126}

12.4.3.7 Immunoassays for Other Illegal Drugs

Immunoassays have been developed to screen for the presence of other illegal drugs, including cannabinoids, LSD, and prescription drugs such as propoxyphene, methadone, and methaqualone. With the exception of cannabinoids and LSD, all of the analytes are readily detected by either ToxiLab A or GC basic drug screens. Cannabinoid and LSD assays may be included in a standard screening protocol or may be reserved for cases involving an issue of possible behavioral toxicity, since those are not known to contribute to either fatal intoxications or deaths attributable to natural causes.

12.4.3.8 *Chromatographic Methods*

Chromatographic methods are used to expand the range of a drug screen beyond those drugs detectable by the immunoassays. The extraction system should be selective for basic drugs, and neutral substances will also be extracted.^{47,58,62,71–76,127–130}

ToxiLab A for Urine and Gastric Contents

The ToxiLab A system for basic drug detection is a powerful tool for drug screening in urine or gastric contents.^{55–57,131} The four-stage visualization process, combined with R_f and detection of metabolite patterns, adds considerably to the confidence in drug identification. Sensitivity for many drugs is on the order of 0.5 to 1.0 mg/L, which is satisfactory for screening urine or gastric samples. The ToxiLab A can detect nearly 150 drugs and their metabolites.

Alternatives to ToxiLab

A screen for basic and neutral drugs by CG with a nitrogen/phosphorus detector (NPD) is an alternative to ToxiLab TLC for a laboratory having sufficient GC capacity.^{47,71,74–76,82,127} GC is much more sensitive than TLC, having limits of detection on the order of 0.01 to 0.10 mg/L from 1 mL of sample. GC can be calibrated to presumptively identify hundreds of drugs and drug metabolites, and the NPD data can reveal other unidentified nitrogen-containing substances that may be characterized by additional analysis of the extract by GC/MS.

The Trinders test is added to the screen to detect salicylate from aspirin, a common drug and one that is sometimes taken for suicidal purposes. It may be eliminated if the screen is intended only to evaluate potential behavioral toxicity. The chemical tests for ethchlorvynol and chloral hydrate fill another gap in the screening protocol, since these drugs are not detected by immunoassay or in chromatographic screens for basic drug or volatiles. Figure 12.4.2 illustrates the analytical scheme for routine cases with both urine and blood submitted to the laboratory.

12.4.3.9 *Gastric Contents vs. Urine*

Often, urine is not available for testing because the bladder was empty at the time of autopsy. In such cases, an extract or filtrate of gastric contents may be substituted. However, a gastric drug screen alone may not be sufficient to exclude all potentially relevant substances. Drugs that are typically administered parenterally, smoked, or insufflated may not diffuse into the stomach in detectable amounts, so blood or plasma analysis with immunoassays for opiates and benzoylcegonine is often required to detect those substances.

Drugs taken hours before death may not remain in the stomach. However, some quantity of a basic drug will diffuse into the stomach from blood and become ionized, and thus remains there. The resulting concentration in the stomach contents is determined in part by the drug's concentration in blood and in part by its pKa. For optimum sensitivity, a gastric content drug screen may be combined with immunoassays on plasma, vitreous humor, or blood for barbiturates, benzodiazepines, benzoylcegonine, opiates, and a basic drug screen of blood by GC-NPD. The following protocols, which employ tests on gastric contents and blood (or plasma), can be used in place of a urine drug screen. The same blood test panel may be used when gastric contents are not available, or applied to tissue homogenates when blood is not available.

Immunoassays can usually be performed directly on unhemolyzed plasma or vitreous humor. Even hemolyzed plasma and post-mortem whole blood can be tested directly if FPIA or RIA is used.^{50,52,132–145} If results are unsatisfactory, simple dilution with an equal volume of assay buffer is often sufficient to render an analyzable sample. If FPIA or RIA is not available in the laboratory, blood may be screened with spectrophotometry-based immunoassays, although hemoglobin and

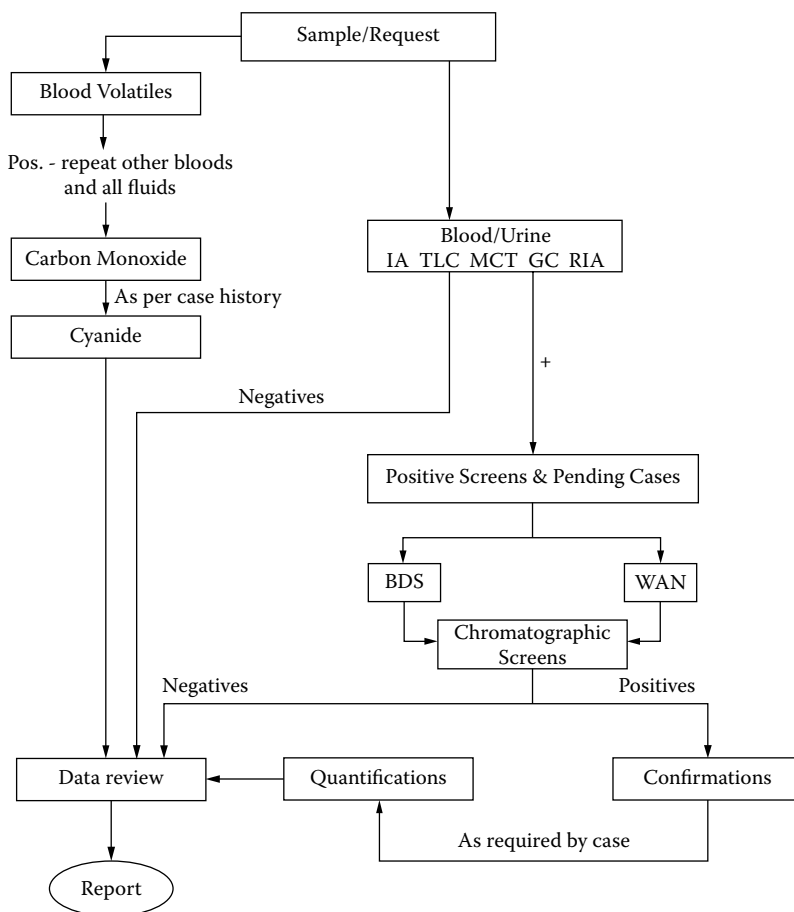

Figure 12.4.2 Flowchart for routine toxicology cases.

other proteins must first be precipitated by addition of acetone, methanol, or acetonitrile. The centrifuged supernatant from such treatment can be assayed against similarly prepared calibrators.^{49–52,146–154} When applied to blood, plasma, or vitreous humor, immunoassays should be calibrated to a lower cutoff threshold than that used for urine screening. Cutoffs, on the order of 50 ng/mL (500 ng/mL for barbiturates) will yield some false positives. Considering the variations in cross-reactivity for analytes of interest (e.g., benzodiazepines), some false-positive immunoassay results may be acceptable in the interest of minimizing false negatives. Any positive immunoassay result must, of course, be confirmed if it is to be reported. If the case may involve lethal toxicity, immunoassays for acetaminophen and salicylate should be added to the panel.

12.4.3.10 Screening with Gas Chromatography

GC for basic drugs in blood is more sensitive than a basic drug screen on gastric contents, but is also more labor intensive. It may be included in a general drug screen whenever urine is not available or it may be reserved for cases where intoxication is indicated by the investigation, and gastric contents yield negative screening results. Figure 12.4.1 illustrates general screening protocols for various combinations of post-mortem samples.

When initial chromatographic screening tests reveal an unidentified spot on TLC or a response from GC that does not match any standard, extracts may be further screened by GC/MS in the full scan electron-impact ionization mode.^{80,82,83,100,155–163} Reconstructed ion chromatograms are

inspected for spectra that indicate exogenous (i.e., xenobiotic) substances. Suspect spectra are compared with the instrument's computerized libraries of drugs, poisons, and their metabolites. In addition, spectra may be visually compared with published compilations of mass spectral data.^{164–169} Whenever a tentative identification is made, the unknown and reference spectra must be visually compared to verify their identity. GC/MS is the most complex method of screening for drugs and poisons, and also the most expensive. The analyst must have a considerable amount of training and experience to reliably perform GC/MS screening.

To provide adequate support for a medical examiner's office the toxicology laboratory should periodically assess the prevalence of drugs in the population served, and adjust its offering of routine tests accordingly. Certain drugs are more prevalent in various localities due to supply routes, ethnic practices, and demand. Changing patterns of drug use may be identified through crime laboratory statistics and various epidemiological monitoring programs, such as the Drug Abuse Warning Network (DAWN) and the community-based Drug Epidemiology Network. In Europe, the www.emcdda Web site offers similar information for the EU countries.

12.4.3.11 Screening with Liquid Chromatography

Many drugs that cannot be detected by GC can be detected by high-performance liquid chromatography (HPLC). HPLC separates analytes in solution, at or near ambient temperature, and therefore can be used for drugs that are too thermolabile or polar to be analyzed by GC. Furthermore, chemical derivatization is rarely, if ever, required prior to analysis of drugs by HPLC. While most, but not all drugs, absorb ultraviolet (UV) light sufficiently well to be detected by a UV detector, a UV spectrum usually does not give sufficient information on its own, for a forensically valid identification. Therefore, the preferred detector increasingly is becoming the mass spectrometer. However, LC/MS has not yet become widely accepted as a useful screening technique for two reasons. First, LC/MS instrumentation continues to cost approximately twice as much as a GC/MS instrument. Second, and more important, it has been very difficult to generate reference libraries that are universally useful. Although, perhaps arguably more useful than UV spectra, most LC/MS spectra lack the detail of typical electron impact (EI) GC/MS spectra, and worse, relative abundances across the spectrum can vary with pH and ionic strength.

12.4.4 The General Unknown

Cases in which a toxic cause of death is suspected but where a specified toxic agent is not known are referred to as general unknowns, and require an open-ended search for poisons. The first step in investigating a general unknown is to carefully examine the medical records, case history, autopsy findings, and scene observations for evidence of specific toxins, or of a toxic mechanism.^{1–3,5–9,30,170,171}

The case history and medical records may describe symptoms characteristic of a particular pharmacologic category. Cardiac rhythm disturbances, respiratory rate and pattern, pupil size and responsiveness, condition of reflexes, convulsions, and any other pre-mortem symptoms may suggest a toxic mechanism that excludes some toxins from a long list of possible agents.

Autopsy findings may also provide guidance. The condition of the gastric and esophageal mucosa may suggest or exclude corrosive poisons. The presence of massive pulmonary edema may indicate preterminal respiratory depression. Hepatic necrosis may indicate acetaminophen or *Amanita* mushroom toxicity, among other agents. Needle punctures and, especially, "track marks" indicate possible intravenous drug overdose. These and other observations, properly interpreted, can narrow the focus of the analytical search.

Consideration of the place where death occurred, or where the terminal symptoms appeared, may suggest toxic agents. Scene investigation can yield valuable clues. For example, the death of a jewelry store employee may have resulted from exposure to cyanide, which is used in jewelry

manufacture. Other employment settings have associated chemical hazards that should be recognized when planning a strategy for investigation of a workplace death.

In the home, other toxic exposures are more likely. Drugs, pesticides, and other chemical products for household use are possible agents. Also, drug misuse at home can result in accidents or fatal intoxication. Reports of witnesses can also give valuable clues. What was the deceased doing at the onset of illness? When was the deceased last seen alive? Was the deceased behaving normally, or was intoxication indicated? Was there a complaint of feeling sick? Eliciting such observations may make it possible to shorten the list of possible drugs.

The volatiles screen by headspace GC, while designed to test for the common alcohols and acetone, can also detect other volatile chemicals such as toluene and other solvents and volatile anesthetics. Drug screening tests are essential to rule out drug intoxication, and chromatographic screens can detect many other chemical substances besides drugs. GC/MS is a mainstay of screening protocols for general unknowns. Semivolatile organic compounds can be identified by computerized comparison of their mass spectra with libraries containing over 50,000 spectra of pesticides, drugs, and industrial chemicals. Figure 12.4.3 illustrates a strategy for analysis of cases where classification is pending the outcome of toxicology testing.

Tests for drugs and poisons not detected by the basic strategy can be added to the protocol for general unknowns. Selective immunoassays are available to test for cardiac glycosides, LSD, fentanyl, haloperidol, aminoglycoside antibiotics, and anticonvulsants. Clinical laboratories can provide assistance with tests for potassium, lithium, iron, and insulin or C-peptide. Toxic metals and nonmetals can be detected by atomic absorption spectrophotometry, and classical inorganic qualitative tests can be used to screen for toxic anions on a dialysate of urine, blood, or stomach contents. Other drugs that do not chromatograph well by GC may be detected by HPLC.

The following guidelines should be observed in approaching the general unknown:

1. If specimen selection and quantity are not limiting factors, then the objective should be the broadest screen possible with available technology.
2. The blood and vitreous fluid alcohol content should be determined before or simultaneously with other analyses.
3. Blood alcohol analyses should be performed by headspace GC, utilizing an internal standard. This does not preclude possible confirmation by some other procedure.
4. If carbon monoxide is to be determined, this should also be done prior to drug screening procedures.
5. In the absence of background information on a given case, the selected analytical scheme should provide the best chances of successfully finding a drug or poison. That is, the more commonly encountered drugs and poisons should be sought before the more rarely encountered ones are considered.
6. In the event that specimen selection and quantity are limited, it will be necessary to plan assays more carefully. Immunoassay procedures should be applied early in the scheme if proper samples are available.
7. All assays should be considered with the intent of subsequently confirming positive findings by another independent procedure. This means, for example, that if specimen size is a limiting factor, then different stages of a general screen should be performed sequentially rather than in parallel.

12.4.5 Confirmation

12.4.5.1 *What Confirmation Is Necessary, and Why*

Courts require that the opinions expressed by toxicologists be of a “reasonable scientific probability,” that the identity of reported substances be known with “scientific certainty,” and that quantitative values be accurate to a stated statistical probability. Screening tests provide tentative identification of drugs and poisons. The forensic standard for conclusive identification requires that their identity be confirmed by additional tests.¹⁷²

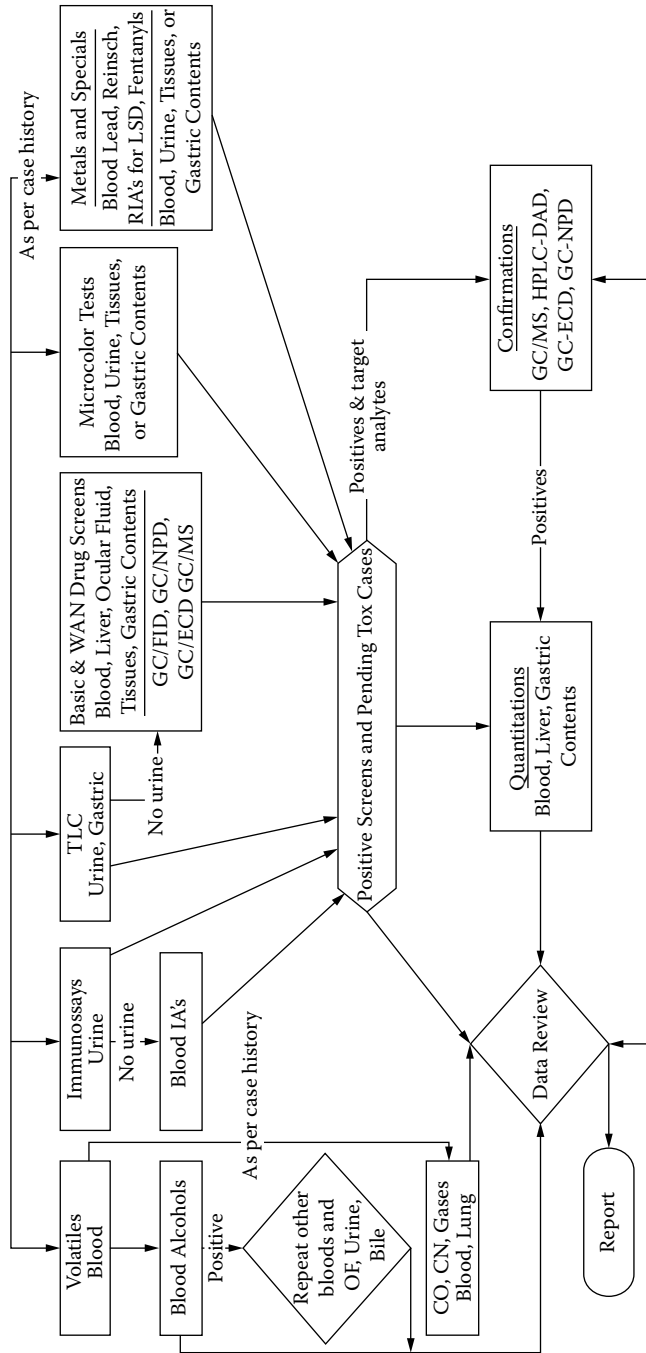

Figure 12.4.3 Analytical strategies for post-mortem toxicology screening in the pending tox case.

The first analytical indication of the presence of a particular drug is usually obtained from an immunoassay, a chromatographic screen (e.g., TLC), or a spot test. The initial test may point to a particular drug, or class of drugs, such as barbiturates, benzodiazepines, or opiates. The confirmatory test must clearly identify the specific drug and/or its metabolite(s). Confirmatory methods may include gas chromatography with flame ionization (GC-FID), electron capture (GC-ECD), and nitrogen-phosphorus (GC-NPD) detectors, HPLC, UV spectroscopy, GC/MS, and other hyphenated techniques such as MS/MS coupled to either a GC or LC sample introduction system.

Any chemical test can be subject to errors that may cause a false-positive result. Immunoassays can cross-react with substances other than the target drug. Chromatographic methods can have interfering substances that produce a signal or spot at the same time and place as a target analyte. Even GC/MS can yield false positive results if a sample is mislabeled or contaminated in process, or by carryover from a preceding injection, or if the spectrum does not have a unique fragmentation pattern. For example, amitriptyline and cyclobenzaprine have similar retention times and yield fragmentation patterns that are nearly identical. They may be confused if the molecular ion cannot be discerned.

In recognition of the possibility of a false-positive result from a single test, it is necessary that all potentially significant results be confirmed. Confirmation requires at least one additional test based on a different chemical detection principle, with high specificity and sensitivity at least equal to the initial test.¹⁷² The essence of confirmation is to assemble a sufficient body of evidence such that a technically competent independent reviewer would agree with the conclusion.

The requirement for two or more chemically distinct methodologies is based on the concern that chemical similarity could cause a false-positive result in one type of test, and may also influence another test with a similar chemical principle. A radioimmunoassay cannot confirm enzyme immunoassay results since the chemical properties responsible for antibody binding may affect the antibodies in both tests similarly. Likewise, two similar GC columns such as 1 and 5% phenyl-methylsilicone (DB-1 and DB-5) would not serve to confirm one another, because the polarities of the two liquid phases and, hence, the elution orders of most drugs are similar.

A combination of less specific chromatographic procedures (e.g., TLC, GC-NPD/ECD, or HPLC) can be used to confirm screening results from immunoassay or spot test results. A second chromatographic method based on a different chemical principle may be used to confirm a presumptive finding from a chromatographic screening test (e.g., TLC and GLC or HPLC and GC-NPD/EC). Derivatization of the presumptively identified drug can alter its chromatographic behavior sufficiently to permit confirmation by reanalysis in the same chromatographic system. Some screening procedures, such as GC/MS, identify specific compounds. Even here, a second test on a separate aliquot should be performed to "verify" the analyte and ensure that no human error in sample handling or analyses has occurred. Re-injection of the same extract would not be sufficient. An exception to this rule would be limited sample volume precluding repeat analyses.

In post-mortem toxicology, confirmation tests are often applied to specimens other than the one used for screening. By employing a quantitative confirmatory method, the analyte is simultaneously confirmed and quantified. For example, a presumptive finding of diphenhydramine in urine by TLC may be confirmed by a quantitative GC procedure applied to blood.

Some additional illustrative examples of confirmation follow:

1. An immunoassay positive for opiates in urine, followed by a GC/MS analysis of urine to identify the specific drug(s).
2. An immunoassay positive for benzodiazepines in urine, followed by an analysis of blood by GC-ECD to identify the specific drug(s).
3. A drug such as amitriptyline detected by TLC in urine or gastric contents followed by GC-NPD analysis of blood with relative retention times matching the suspected drug, ideally on two columns of differing liquid phase. A quantification of the drug by HPLC would give additional confirmatory evidence as would detection of metabolites of the presumptively identified drug by TLC or GC.

4. Immunoassay positive for cocaine metabolite in urine or blood with detection of parent cocaine in blood by GC-NPD.
5. In some cases, such as blood volatiles analysis, GC headspace analysis can be correlated as relative retention times on two GC columns of differing polarity (giving a different elution order) to confirm an identification. However, novel or rarely detected analytes such as toluene or 1,1,1-trichloroethane may require further confirmation by headspace GC/MS.

12.4.5.2 When Is Confirmation Necessary?

In general, any finding that could reasonably be questioned, or adversely affect insurance coverage or the reputation of the deceased, should be confirmed before it is reported. The greater the significance of a finding to the case, the more important it becomes to confirm that finding to absolute certainty by GC/MS, if possible.

- When the substance is potentially related to the cause and manner of death
- When the detected substance is an illicit drug such as marijuana, cocaine, methamphetamine, or PCP, since labeling an individual a possible drug abuser has serious sociologic and legal implications^{173–176}
- Any prescription drug that is not known to have been prescribed for the deceased

12.4.5.3 When Is Confirmation Unnecessary?

When the substance presumptively detected has no relationship to the cause or manner of death, and when the detected substance carries no stigma, if reported, confirmation may not be needed. Over-the-counter medications, with no behavioral toxicity, usually do not require confirmation except when it is suspected that they may have contributed to toxicity. For example, salicylate or acetaminophen need not be confirmed in traumatic death cases, but should be confirmed in cases pending toxicology or suicidal intoxications.

Medications commonly administered during resuscitation, such as lidocaine and atropine, do not need confirmation if the deceased received such treatment before being pronounced dead. Prescribed medications that the deceased had been taking, and which are not related to the cause or manner of death, may not require confirmation either, since their presence in biological specimens is consistent with the history. Any substance reported without confirmation should be identified in the report as an unconfirmed presumptive finding.

12.4.6 Gas Chromatography-Mass Spectrometry

Today, GC/MS is generally accepted as unequivocal identification for most drugs, providing the best confirmatory information when performed correctly.^{177,178} However, GC/MS assays can be performed in many ways, depending on the specific requirements and use of the results. Pharmacokinetic studies generally employ chemical ionization with single-ion monitoring to obtain optimum sensitivity. In such studies, the target drug is expected to be present, so criteria for identification need not be so rigorous, but single-ion monitoring is not usually considered sufficient for forensic purposes. GC/MS methods for the confirmation of illegal drugs of abuse in urine most often use electron impact ionization and multiple-ion monitoring to obtain conclusive results.^{177–181} The more traditional MS identification criterion calls for matching retention times and full-scan electron impact mass spectra of the unknown with a standard.

Whether forensic samples should be analyzed by full-scan data acquisition, or by selected ion monitoring, is a matter of contention. The debate really comes down to one underlying question: How much spectral and chromatographic information is needed to provide a scientifically and legally defensible identification? Is a full-scan spectrum necessary? If selected ion monitoring is acceptable, how many ions must be monitored? Unfortunately, there are no simple answers. A

good-quality, full-scan mass spectrum that matches a reference spectrum clearly constitutes a more definitive identification than ion current profiles of a few selected ions at the correct retention time.

Cody and Foltz have stated that the specificity of a GC/MS assay depends on many factors, including:

1. Choice of internal standard. The role of the internal standard in the overall analytical process cannot be overemphasized.^{182–187}
2. Selectivity of the extraction procedure.
3. Choice of derivative, where appropriate.^{188–190}
4. Efficiency of the GS separation.
5. Method of ionization.
6. Relative uniqueness of the analyte's mass spectrum or the chosen ions to be monitored.
7. Signal-to-noise ratio of the detected ions.¹⁹²

Using GC/MS in the scanning mode, as both a screening and definitive identification methodology, has become quite common.¹⁶³ If the drug is an unknown, full-scan mode is the method of choice. Further comparison of the unknown's full mass spectrum with reference spectra will be necessary. Mass spectra are tentatively identified by a computerized library search and visually compared by an experienced analyst.^{80,81,161–163}

GC/MS with selected ion monitoring (GC/MS-SIM) is commonly used to confirm the presence of drugs and/or metabolites in post-mortem samples.^{180,191} A well-designed assay, involving the selected ion monitoring of three or more abundant and structurally diagnostic ions, combined with specific requirements for the analyte's retention time relative to a suitable internal standard or calibrator, is regarded as a reliable identification.¹⁹² Even fewer ions can provide an acceptable identification if the assay employs a highly selective extraction procedure or selective mode of ionization, such as ammonia chemical ionization.

GC/MS-SIM assays are extremely useful to confirm or exclude the presence of a suspected analyte that may have been indicated by history or screening results. However, target compound analyses such as GC/MS-SIM will detect, or exclude, only a limited number of related chemical compounds or classes of drugs. A reference standard and control materials of the target analyte must be analyzed within the same batch. Selected ion monitoring typically provides signal intensities that are 10- to 100-fold greater than those from full-scan analysis performed on quadrupole instruments. SIM analyses are therefore better adapted for quantitative measurements. Selected ion monitoring is generally less susceptible to interferences from co-eluting compounds than an assay employing full-scan recording. However, unlike full-scan spectral acquisition, a selected ion monitoring assay will not detect unsuspected drugs that may be of toxicological significance.

Standards adopted for conclusive drug identification include (1) the appearance of the monitored ions at a correct retention time, (2) acceptable intensity ratios among those ions. The retention time and ion intensity ratios observed in the test sample are compared with those established from the calibrator(s) containing the target analyte, at a suitable concentration, incorporated in the same analytical batch.

12.4.6.1 Qualitative GC/MS-SIM Determination Criteria

To qualitatively identify a compound by selected ion monitoring (SIM), ion chromatograms are obtained from the reference compound for the primary ion and two or more qualifier ions. The criteria below must be met for a qualitative identification of an unknown:

1. The characteristic ions of the compound must be found at maxima in the same scan or within one scan of each other.
2. The retention time of the unknown compound's mass spectrum must be within $\pm 2\%$ of the retention time of the authentic compound or deuterated internal standard.

3. The ratios of the SIM peak areas must agree within $\pm 20\%$ with the ratios of the relative intensities for those ions in a reference mass spectrum from a calibrator analyzed on the same run by the GC/MS system.

These criteria should be kept in mind when making compound identification decisions. In addition Dr. Rodger Foltz has proposed the following helpful guidelines:^{160,192-194}

1. Agreement among the relative ion intensities within a small mass range is more important than for those encompassing a wide mass range.
2. The higher mass ions are generally more diagnostic than those occurring at low mass.
3. No prominent ions in either spectrum (those with relative intensities above 10%) should be totally missing from the other spectrum, unless they can be attributed to an impurity.

12.4.6.2 Potential Problems with GC/MS Analyses

Several problems may be encountered in GC/MS analysis. The mass spectral library may give erroneous identifications when concentrations near the detection limit are analyzed, or when chromatographically interfering substances are present, or when isomers are analyzed. Even MS with a full fragmentation pattern may not provide adequate confirmation, either because several drugs have very similar fragmentation patterns, as the barbiturates, for example, or because the drug may exhibit only one major peak consisting of a low mass fragment ion in its mass spectrum, such as the tricyclic antidepressants.

When using the SIM mode, a considerable gain in GC/MS sensitivity can be achieved by focusing on the most abundant ion, and two or more other characteristic ions. However, many illegal drugs or metabolites (and numerous other commonly used drugs, e.g., antihistamines, local anesthetics, some beta-blocking agents, etc.) have similar EI mass spectra, showing a common base peak and weak molecular ion signals. Many elute over a wide range of retention times; others may have closely related retention indices.

The complexity of biological matrices encountered in post-mortem cases, such as "blood," tissues, gastric contents, and hair/nails, necessitates well-designed, and often multistep, sample treatment procedures.¹⁹⁵ This is especially true when utilizing procedures based on physicochemical properties of drug/metabolites. Suitable sample preparation is the most important prerequisite in the GC/MS of typical post-mortem samples. It involves isolation and, if necessary, cleavage of conjugates and/or derivatization of the drugs and their metabolites. Derivatization steps are necessary if relatively polar compounds such as metabolites are to be screened or confirmed.

12.4.7 Liquid Chromatography-Mass Spectrometry

LC/MS is fast becoming an important technique in forensic toxicology, despite its increased cost over GC/MS.²²⁵⁻²³⁰ For a long time, the combination of HPLC and MS was not an alternative because of interface problems. Now when this obstacle has been overcome by different innovations, LC/MS has become increasingly popular both for screening purposes and for sensitive and specific confirmation analyses. Many drugs cannot be analyzed by GC/MS because they are either thermolabile, or are too polar or insufficiently volatile to chromatograph well, if at all. In contrast, virtually any drug can be analyzed by LC/MS after development of a suitable method. Other than the issue of cost, the only disadvantage of LC over GC is that LC separations usually require more development time than GC separations. The comments in Section 12.4.6, above, generally apply to LC/MS analysis, especially in regard to SIM analysis. As with GC/MS, so-called "hyphenated" techniques may be used, such as LC/MS/MS. Tandem MS-MS instruments have the enormous advantage of being able to provide a much higher degree of specificity than LC/MS alone. The first mass spectrometer in the LC/MS/MS system generates a conventional mass spectrum. One specific mass is then allowed to pass through into a separate collision cell where it can be ionized

further. Either the entire mass spectrum of that chosen ion may be displayed, or a single ion isolated in SIM mode. Tandem MS techniques such as LC/MS/MS are particularly useful for post-mortem forensic work because they minimize interference from endogenous compounds such as putrefactive products. LC/MS/MS-TOF (time-of-flight) instruments offer a further degree of specificity because of the increased specificity imparted by the medium to high mass resolution of TOF instruments. Of course, the major drawbacks of LC/MS/MS and LC/MS/MS-TOF instruments are considerably increased cost, and complexity of operation, often requiring a dedicated operator. Having stated that, the development of a method for a particular analyte is generally easier with LC/MS than with GC/MS because standards with reference compounds can be directly injected and calibration curves can readily be constructed. A special feature that the operator must keep in mind is that a change in pH to adjust the chromatography will also affect the charge of the compounds at the time for ionization, and hence influence the mass spectrometric detection.

Different interface systems are available. The most utilized alternative is atmospheric pressure-positive electrospray ionization (API-ES), and a number of applications in forensic toxicology with this methodology has been reported.^{231–235} Alternatively, atmospheric pressure-chemical ionization (APCI) can be used. Both these variants of LC/MS instrumentation cover a wider spectrum of polar and nonpolar drugs than GC/MS analysis can offer, and API-ES also allows for analysis of molecules with higher masses. APCI MS/MS has been shown to be useful for sensitive screening of certain classes of drugs such as benzodiazepines and hypnotics,²³⁶ and beta-blockers.²³⁷

12.4.8 Method Validation

Bioanalytical methods, based on a variety of physicochemical and biological techniques, such as chromatography, immunoassay, and mass spectrometry, must all be individually validated prior to and during use to generate confidence in the results.^{196–210} Method validation is discussed in Chapter 12.5.

12.4.9 Quantification of Drugs and Poisons

When you can measure what you are speaking about and express it in numbers, you know something about it; but when you cannot express it in numbers, your knowledge is of meagre and unsatisfactory kind.

— Lord Kelvin (1824–1907)

Screening and confirmation (qualitative) tests establish the presence of a specific substance; quantitative tests measure the amount of that substance in a particular specimen. Qualitative information alone can demonstrate that the deceased was exposed to the substance before death, and may even enable the toxicologist to offer an opinion regarding the ante-mortem interval in which the exposure probably took place. However, quantitative information is often required to form an opinion whether or not the exposure was sufficient to cause behavioral toxicity or death. Drug concentrations in post-mortem tissues, or fluids, must be related to reference values derived from other cases.^{5,211–215}

12.4.9.1 What Should Be Quantified?

Substances should be quantified only when necessary for interpretation. Most quantitative assays are separate, labor-intensive procedures that measure only one drug or group of similar compounds. Quantifying substances that, by their nature, could have no conceivable bearing on the issues of the case is a waste of time and resources. For example, drugs with no psychoactivity, such as acetaminophen, should not be quantified in a motor vehicle accident driver victim, while diphenhydramine, an antihistamine with sedative side effects, should. On the other hand, if the victim was a passenger, diphenhydramine would not require quantification. In deaths from asthma or

epilepsy, the laboratory should quantify theophylline or anticonvulsant, respectively, to determine whether or not they were within or below the therapeutic concentration range.

In general, substances that can cause behavioral toxicity should be quantified. In most natural deaths, it is important to know that the concentration of a prescribed or therapeutic drug is not excessive. Semiquantitative information, derived from blood screening tests, is often sufficient to make the assessment. Only if the concentration estimate indicates an excessive amount would a quantitative assay be required. Poisons such as carbon monoxide, cyanide, and heavy metals should always be quantified in appropriate specimens. Tests for ethanol usually yield both qualitative and quantitative data, which should be reported if above the laboratory's administrative cutoff (usually 0.01%).

Cocaine should always be quantified. Its concentration is usually important and its instability in storage may prevent subsequent analysis if it is not quantified soon after detection. Other drugs or poisons that are unstable in storage should be quantified before their decomposition renders the analysis unreliable. In a case that is pending the outcome of toxicology testing, any detected drugs or poisons and their metabolites should be quantified, unless it is clear from the circumstances of the case that a particular substance did not play a role in the cause or manner of death.

When resuscitation has been attempted, lidocaine and atropine may be detected in post-mortem blood. Unless a medication error is suspected, or the quantity appears to be excessive, it is not necessary to quantify them. Nor is there any need to quantify caffeine and nicotine, unless toxicity is suspected or screening tests indicate that an abnormally large amount of either is present.

In most cases a drug's metabolites are just as important to quantify as the parent compound. The ratio of parent drug to its metabolite often indicates the state of pharmacokinetics in the individual case. For example, a ratio greater than 1 for amitriptyline/nortriptyline may indicate an acute ingestion or short interval from ingestion to death, while a ratio of 0.3 in a propoxyphene/norpropoxyphene case may indicate a chronic exposure.

Active or toxic metabolites of a drug or poison are always measured, but inactive metabolites may also be important. Their presence may shed light on the pattern of drug use. High concentrations of benzoylecgonine indicate accumulations from multiple doses. Low concentrations suggest that only a few doses were taken or that there has been a long interval since the last dose. Furthermore, there is some evidence that benzoylecgonine may be a vasoconstrictor, so it may contribute to the hypertensive effects of cocaine use.

12.4.9.2 Specimens for Quantification of Drugs and Poisons

The choice of the sample for quantitative analysis is very important.²¹⁶ Often it is sufficient to quantify drugs or poisons in blood only. If toxicity is not suspected, a blood quantification can verify that the drug was present, and that its concentration was consistent with therapeutic use. Also, when a drug concentration is clearly in the lethal range, and poisoning or overdose is suspected, a blood determination may be sufficient. It may not be necessary to quantify brain morphine levels in an intravenous heroin user, found dead with syringe, tourniquet, and "cooker" present, with autopsy evidence of pulmonary edema, and a high concentration of morphine in the blood, to support a conclusion that death was caused by a heroin overdose. Likewise, a 15 mg/L blood amitriptyline concentration, in a case accompanied by a suicide note, is sufficient to define overt toxicity, regardless of potential post-mortem diffusion.²¹⁶ Carbon monoxide should be measured in blood, its site of action. Other specimens are likely to give negative results. One exception, not related to drug abuse, is the analysis of skeletal muscle specimens for carbon monoxide to assist in the differentiation between entrance and exit gunshot wounds.

Tissues that selectively take up a particular drug class may have a much higher concentration than that found in blood. For example, volatile anesthetics, cocaine, marijuana, tricyclic antidepressants, and other lipid-soluble substances are preferentially absorbed into the fatty tissues of the brain and liver, while digoxin and other cardiac glycosides are taken up by cardiac muscle. Figure

12.4.2 and Figure 12.4.3 show the relationship of quantifications to the overall process of post-mortem toxicology analysis.

12.4.9.3 Quantification: Procedural Issues

Instruments

Many of the instruments used for screening tests can also provide accurate quantitative data. Immunoassays designed for therapeutic drug monitoring (TDM) (e.g., serum assays for phenobarbital, theophylline, and phenytoin) are specific, and yield accurate results with most post-mortem specimens.^{144,217} GC, HPLC, GC/MS, and LC/MS are readily adapted for quantification. Spectrophotometric methods are useful for some analytes, such as ethchlorvynol and heavy metals.¹ However, their utility is limited because many drugs have metabolites or breakdown products with similar spectra (e.g., phenothiazines), so relative contributions of the parent drug, and active and inactive metabolites, to the signal cannot be segregated and assessed.

Sample Preparation

Blood and other fluids are usually extracted with no pretreatment other than dilution. GC screening tests can provide an estimate of the concentration of the analyte. If the estimated concentration is above the upper limit of linearity of the assay, the sample must be diluted with water, buffer, or negative control matrix and thoroughly mixed to bring the analyte concentration into the dynamic range of the assay. Homogenates of tissue samples are prepared in a blender or a tissue homogenizer in water or a buffer usually in a 1:2 to a 1:5 ratio. These homogenates deteriorate rapidly so they are usually used within 2 weeks or less, and the remainder discarded. Gastric contents are weighed or measured by volume, homogenized, and appropriately diluted.

With the exception of some immunoassays, samples are usually extracted with organic solvent to isolate the compounds of interest from the biological matrix. Often, liquid–liquid extraction is used, with back-extraction to eliminate lipid interference. Recent advances in solid-phase extraction technology have made possible the application of these techniques to the analysis of blood and tissues. The speed and efficiency of solid-phase extractions make them an attractive alternative to liquid–liquid extraction procedures, and their use is expanding in post-mortem toxicology. However, lot-to-lot inconsistencies in solid-phase extraction columns can cause quantitative methods to fail, due to poor recovery of analytes. Therefore, it is extremely important to evaluate each new batch of columns before risking wastage of, sometimes limited, samples.

Duplicate samples should be analyzed through the entire procedure to demonstrate the reproducibility of the result. If the difference between duplicate analyses is greater than the two standard deviations for the method, the analyst should suspect that an error occurred in one or both. Additional analyses should be performed to determine an accurate result with acceptable precision.

Internal Standard

Most quantitative procedures employ one or more internal standards to compensate for variations in extraction efficiency, injection volume, and changes in detector sensitivity. An internal standard is a substance with chemical properties similar to the target analyte. It is added in identical quantity to each sample and standard before the extraction process. The internal standard is extracted along with the analyte, so that any loss of analyte in the extraction process will be compensated for by a proportional loss of internal standard. The assumption is that the ratio of analyte to internal standard does not change. Selection and evaluation of the internal standards is a critical component for the development of a quantitative procedure.^{184,218–222} Method development and validation and the selection of internal standards are discussed in Chapter 12.5.

12.4.10 The Review Process

Individual cases should be reviewed periodically to assess the status of the investigation and the quality of the acquired data. Reassessment may suggest the need for additional tests. Before a report is issued, the entire case file must be reviewed to ensure that results are forensically acceptable and that sufficient data have been gathered to determine whether, and to what extent, drugs or poisons influenced the cause and manner of death. When testing has been completed, the toxicologist reviews the file one final time to ensure that nothing has been overlooked.

12.4.11 Pending Toxicology Conference

In cases where the cause of death is not obvious, and determinations have been put on hold pending the results of toxicological testing, the toxicologist and pathologist together review the investigation, autopsy, and toxicology results. When both are satisfied that the toxicology results answer the questions pertinent to the case, a final toxicology report is issued. The need for communication and teamwork for an effective system cannot be overemphasized.^{1-5,223,224} Refer to Figure 12.4.3 summarizing the analytic strategies for drug screening in “pending tox cases.”

12.5 QUALITY ASSURANCE IN POST-MORTEM TOXICOLOGY

Wilmo Andollo, B.S.

Quality Assurance Officer, Dade County Medical Examiner Department, Toxicology Laboratory, Miami, Florida

12.5.1 Introduction

The essence of the post-mortem forensic analysis is to characterize a subject's biological tissue in terms of toxic chemical content. Based on the analytical result, an opinion can then be formed about the influence the toxic substance may have had on the subject. Since the result of any chemical analysis carries with it an uncertainty that is inherent in all measurements, an attempt must be made to control and measure the factors that influence that uncertainty. Only when these factors are measured and controlled can the analytical results be deemed reliable.

The quality assurance program is established to ensure the public that the results generated by the laboratory are reliable. This is crucial in a forensic toxicology laboratory since the analytical results are closely scrutinized in a court of law, where truth and impartiality must be authenticated for the public good. A comprehensive quality assurance program will provide an expert witness with details concerning the measurable factors that affect the analytical result. These factors include personnel, the implements of measurement; the quality of materials used; the sample; the analytical method; the analytical instruments; data handling; and reporting.

The *quality assurance* program describes the steps taken to *document* the execution of the quality control procedures; the traceability of reported data to raw data; instrument status during analysis; quality control status; description of the analytical method; qualifications of the analysts; sample integrity and chain of custody; and the corrective actions undertaken for out-of-control

situations. The *quality control* program sets forth the procedures to be taken to *measure* and *control* all sources of random and systematic errors so that limits of accuracy and precision can be established for all analytical methods. It also describes the technical operations undertaken to assure that the data obtained are within the established limits.

12.5.2 Standard Operating Procedures

The standard operating procedure is a written document that outlines in detail the mode of operation of the laboratory. It addresses the relationship of the laboratory with the institutions that it serves, the organizational structure of the laboratory, the quality assurance program, and the chemical hygiene plan. It must address every facet of the laboratory's operation and be available to all laboratory personnel and the public for consultation and review.

The standard operating procedures should address, as a minimum, the following aspects of the laboratory operation:

- Table of organization
- Personnel qualifications
- Precision implements
- Materials
- Sampling
- Analytical methods
- Instruments
- Data
- Reporting
- Proficiency program

The standard operating procedures manual is to be kept up to date and reviewed on a yearly basis to ensure that it typifies the actual operation and that it meets the needs of the laboratory. It is important to archive any old procedures, whether modified or omitted from the manual, so that they can be retrieved for future reference.

The rest of this chapter is devoted to expanding on the subjects that are deemed indispensable in a comprehensive quality assurance program and standard operating procedure manual.

12.5.3 Personnel

The table of organization should be represented by means of a flowchart or schematic diagram. It should include all positions in order of hierarchy, name of persons occupying each position, and accountability of each individual.

The subject of personnel in forensic toxicology laboratories is covered in detail in the SOFT/AAFS Forensic Laboratory Guidelines.¹

12.5.3.1 Continuing Education

The laboratory director is responsible for providing access to continuing education to all employees. Continuing education is essential to the development of the laboratory in maintaining the reliability and integrity necessary in an ever challenging field. New and more potent drugs are being continuously developed along with more advanced analytical techniques and equipment necessary for their detection and identification. Keeping abreast of the new information, be it pharmacological or analytical, is of outmost importance for the subsistence of the forensic laboratory. Membership in professional forensic organizations, such as the American Academy of Forensic Sciences (AAFS), the Society of Forensic Toxicologists (SOFT), the California Association of Toxicologists (CAT), and The International Association of Forensic Toxicologists (TIAFT), provide the venue by which continuing education is not only available but relevant to the forensic laboratory.

12.5.4 Measuring Devices

Regardless of their simplicity, burets, pipettes, volumetric flasks, pipettors, pipettor-diluters, and the analytical balance are used in one way or another in nearly every chemical analysis. They impart the first sources of systematic errors in the analysis. For this reason, it is imperative that their quality, maintenance, and calibration be addressed in the standard operating procedures.

The selection and maintenance of chemical measuring devices and instruments is beyond the scope of this section, but is covered in detail in textbooks of quantitative chemical analysis and instrumental analysis.^{2,3}

12.5.5 Reagents

Chemicals, reagents, solvents, and gases used in the process of executing the analytical procedures must meet minimum quality criteria as required by the analytical method. They should be properly stored, according to manufacturers' specifications or good chemical hygiene practice, in order to maintain their integrity and safety. Special care must be taken to record the receipt date and consider the stability of the reagent before use.

The determination of trace amounts of analytes in complex biological fluids or tissues often requires concentration of organic solvent extracts, which must be analyzed by very sensitive instruments. This circumstance creates a need for high-purity solvents, reagents, and gases to avoid introducing significant amounts of interferences during the analytical process. Commercially available solvents have been developed with special qualities applicable to specific purposes. Examples include solvents possessing low ultraviolet absorption, used in high-performance liquid chromatography and spectrophotometry, as well as solvents with negligible halogenated organic content, required for electron capture detectors or negative ion chemical ionization mass spectrometry. A post-mortem toxicology laboratory should procure the highest quality of reagent possible to minimize the potential for interferences with its analytical methods.

The use of inert, high-purity gases for gas-liquid chromatographs has been an essential part of the operation of gas chromatography since its inception as an analytical tool. The fragile nature of liquid phases in the presence of oxygen (air) at high temperatures and the development of very sensitive detectors such as nitrogen-phosphorus, electron capture, and mass spectrometers, among others, have made the gas quality a priority issue in the operation of the laboratory. Gases with 99.999% purities containing subpart-per-million quantities of air, moisture, and organic compounds are readily available at moderate cost. There are also a variety of products designed to remove or "scrub" contaminants from the gas stream before their introduction into the instrument, which can be utilized if high-purity gases are not readily available. These gas scrubbers should be monitored periodically for proper operation as part of the standard operating procedures.

The preparation of reagents, buffers, and mixtures should be conducted according to the specific instructions in the procedures manual. A reagent log book containing the preparation instructions for the most common solutions provides a convenient way to record their preparation with traceable information such as date of preparation, preparer, stock reagent lot number, and expiration date. This information should always be included in the reagent flask label along with the identification of the solution, its concentration, and any applicable safety recommendation.

12.5.6 Reference Materials

The accuracy of any quantitative analytical procedure depends directly on the purity of the standard used for calibrating the method. Therefore, the analyst must ascertain that the standards, or reference materials, used to prepare the calibrators are chemically pure. The subject of reference materials is discussed in the SOFT/AAFS Forensic Toxicology Laboratory Guidelines.¹

12.5.6.1 Calibrators

Calibrators are materials with which the sample is compared in order to determine the concentration or other quantity.⁶ Methods known to have acceptable accuracy because physical or matrix effects are negligible may be calibrated with certified reference solutions. However, procedural constraints and complex matrix effects of biological samples make the use of certified reference solutions impossible in many routine methods. The calibrators selected for such methods must simulate the physical and chemical properties of the samples in order to compensate for matrix effects during analysis and to be sensitive to important changes in analytical error conditions.

Assay values assigned to calibrators must be sufficiently accurate for the intended use. The uncertainty interval for the assigned concentration value must be small compared to the analytical precision of the method to be calibrated. That is, the absolute error calculated for the assigned value using dimensional analysis must be smaller than the absolute error obtained when the calibrator is analyzed multiple times by the method.⁷

In the forensic laboratory, three types of calibrators may be encountered. The first is use of a reference standard solution as a calibrator when the method has no procedural constraints and matrix effects are virtually non-existent. Certified standard solutions for this type of method can be obtained commercially or prepared in the laboratory with reference materials. This type of method, although rare in the forensic laboratory, can best be exemplified by the analysis of volatiles using headspace techniques with gas chromatography, and the percent purity determination of drug exhibits using ultraviolet spectrometry.

The second type of calibrators includes those obtained from commercial sources as kits to be used in self-contained analytical systems. They are matrix specific and manufactured in bulk under strict quality control. They are carefully designed to perform a specific task under rigorously controlled conditions and are provided with lot numbers and expiration dates. Assays of this type include quantitative techniques by radioactive, enzymatic, and fluorescent immunoassays.

The last type of calibrators encountered in the forensic laboratory are of most concern because they assume the most uncertainty. They are usually employed in analytical assays involving multistep extractions, concentration, derivatization, and complex instruments of analysis and data reduction. These working standards must be prepared in the laboratory from pure reference materials, be diluted with blank sample matrix to resemble the biological sample, and remain accurate enough to convey a reliable measurement when a sample is compared to them. For this reason, every effort should be made to ensure the quality of reference material, the proper maintenance of volumetric implements and balances, and the application of good analytical skills.

The preparation of a calibrator, or working standard, begins with the preparation of a stock solution from the reference drug material. A water-soluble organic solvent that readily dissolves the drug material without adverse reaction is the solvent of choice. Solvents that are not water soluble can be used, but they require additional steps to remove the solvent when further dilutions are made into aqueous biological fluids. A concentration of 1 mg of the un-ionized form of the drug per milliliter of solvent is convenient and adequate for most drugs analyzed. To keep the uncertainty of the calibrator below the variance of the method, it is desirable to know the exact concentration of the stock standard to at least three significant figures. The solutions stored in capped amber vials at -20°C can have long shelf lives if care is taken to allow the solutions to reach room temperature before opening, thus avoiding moisture condensation in the solution. The stability of these solutions must be established periodically. Calibration standards are discussed in the *CRC Handbook of Clinical Chemistry*.⁷

Multilevel Calibration

The calibration scheme used for the purpose of carrying out quantifications of unknown specimens is done with the preparation of a calibration graph that includes a minimum of three different

concentrations and a blank. The concentrations of analyte used to prepare the graph must include the lower and upper limits of required linear response, since linearity must be demonstrated in every assay.

The recommended scheme for the preparation of a set of calibrators has been discussed in the Research Monograph Series of the National Institute on Drug Abuse.⁸

To control for the influence of matrix effects, it is recommended to add the same volume of working stock solution to each aliquot of biological matrix when preparing the calibrators. To do this, a fresh set of working stock solutions is prepared by serial dilutions from the stock solution. Mixtures of drugs and metabolites can also be included in the working stock solution sets.

The calibration graph is obtained by plotting the detector response against the assigned concentration of analyte in the working standard. Chromatographic assays that use internal standards are calibrated by plotting the detector response ratio of analyte to internal standard against the assigned concentration of analyte in the working standard. Using the statistical method of linear regression, the straight line that best fits the points can be determined. The slope of the line and the y-intercept are used to calculate the quantity of analyte in an unknown sample based on its detector response. Figure 12.5.1 shows a representative calibration curve for the analysis of fentanyl. Some calibrations are inherently nonlinear, and therefore it is acceptable to apply a quadratic curve fit rather than force a linear fit to data that is clearly not linear. It is up to the analyst, or as a matter of policy the laboratory, to determine when the degree of nonlinearity is clearly unacceptable. Furthermore, it is good practice for evaluation of the calibration to include reading each calibrator against the established curve. Most calibrators should read within $\pm 20\%$ of the target with perhaps a wider margin as the calibration approaches the origin.

Figure 12.5.1 Multilevel calibration.

Figure 12.5.2 Calibration by method of additions.

Method of Addition

The method of additions is a very powerful calibration technique because the accuracy is independent of matrix effects. The technique requires that replicates of the specimen, instead of blank matrix, be fortified with the different levels of calibrators, along with an unspiked replicate of the specimen serving as the “blank.” All the samples are analyzed by the analytical method as usual. A calibration graph is generated by plotting the detector response of the analyte (or response ratio if using internal standard) against the concentration of the calibrators and plotting the response of the unfortified specimen on the y-axis ($x = 0$). Using the statistical method of linear regression, the straight line that best fits the points is determined and the absolute value of the x-intercept represents the calculated concentration of the specimen. Figure 12.5.2 shows the calculation of azide in blood by the method of additions.

A disadvantage encountered in forensic analysis when using the method of additions is the requirement that multiple aliquots of the specimen be used when forensic samples are inherently limited in size. The use of this method of calibration, therefore, should be limited to situations where a rare analysis is being considered, controls are not available, or when dealing with a particularly difficult matrix.

12.5.6.2 Internal Standards

A suitable internal standard should be used in chromatographic assays such as gas chromatography, high-performance liquid chromatography, and gas chromatography-mass spectrometry. The internal standard can be defined as a substance that is added to all samples (specimens, standards, and controls) in a given assay before processing begins to correct for the many variations that occur in the manipulation of the samples during the entire analysis. Systematic errors affecting the quantity of analyte isolated from the sample will also affect the quantity of the internal standard in the same proportion. Therefore, the ratio of analyte to internal standard at the beginning of the procedure

will remain unchanged throughout. For this concept to hold true, the internal standard must comply with certain qualifications.

First, the internal standard must have chemical and physical characteristics very similar to the analyte of interest. This quality ensures that extraction partition coefficients, formation of derivatives, chromatographic characteristics, and detector response are similar enough not to alter their weight ratio significantly. A compound such as difluorococaine, for example, is not a good internal standard choice for cocaine because its enhanced lipophilicity imparts a very different extraction partition ratio, a different chromatographic characteristic, and a dissimilar response to a nitrogen-phosphorus detector. A compound such as propylbenzoylecgonine, an analogue of cocaine containing a propyl ester instead of a methyl ester, is chemically and physically more satisfactory. From the point of view of extraction and derivatization properties the most appropriate internal standard is an analogue of the analyte that has been labeled with a stable isotope. These substances have identical chemical and physical characteristics to the analyte, so their weight ratio is not affected during the analysis. However, unless the chromatographic system can resolve the two components, these are only useful in analyses by gas chromatography-mass spectrometry.

In addition, it is important to add precisely the same amount of internal standard to each sample. It is not necessary to know exactly the weight amount added as long as it is exactly the same amount. The normal practice is to decide in advance the approximate quantity of internal standard to be added to each sample, since the ratio of analyte to internal standard can be measured most accurately when they are present in similar concentrations. The quantity of internal standard added to the samples, then, should give a concentration intermediate between the lowest and highest expected analyte concentrations. This concentration should be such that the lowest anticipated weight ratio of analyte to internal standard should approximately equal the inverse of the highest anticipated ratio. So, if one desires to measure concentrations of a drug over the range 1 to 1000 ng/mL, the amount of internal standard added should give a concentration of approximately 32 ng/mL (1:32 ~ 32:1000). Some analysts may favor the use of a lower concentration of internal standard to facilitate more accurate measurements of low levels of the drug, since low levels are more difficult to measure than high levels. On the other hand, higher amounts of internal standard can be used to act as a "carrier" to minimize losses of analyte due to adsorption at active sites on the surface of extraction vessels and within the chromatographic column.⁹

12.5.6.3 Controls

A control is a test sample of known concentration that is analyzed along with every batch of specimen to make certain that the analytical procedure performs within the expected limits of variation. Three types of controls can be defined: (1) the negative control, which is drug free and analyzed in qualitative and quantitative methods to show that the method is not introducing a contaminant that may construe a false positive, (2) a positive control, containing the drug at a concentration near the limit of detection and used in qualitative methods to demonstrate adequate performance, and (3) the analytical control(s), containing the drug at a meaningful level(s) and used to monitor the performance of the quantitative method. The intended use of controls is to monitor the performance of a method over a long period of time in an internal quality control program, never to calibrate a procedure. The level chosen for the analytical control should be of clinical and/or forensic importance, such as the significant therapeutic concentration of a drug or the legal intoxication level of ethanol. For assays where many samples are being analyzed, controls should be evenly distributed throughout the run, and one should be included at the end.

Control materials are useful only if applicable to the analytical method used. As is the case with calibrators, the control must simulate the physical and chemical properties of the samples to compensate for matrix effects during analysis and to monitor the performance characteristics of the method. They must be homogeneous to be sensitive to analytical imprecision and stable enough to detect system errors for meaningful periods of time.

The source of control materials and their applications have been discussed extensively in the literature as it pertains to clinical chemistry.^{10–15} The principles discussed, although applicable to some extent to forensic analysis, do not conform to the unique complexity of the specimens encountered in post-mortem work, such as nails, hair, decomposed tissue, and unstable analytes. However, the need to measure the quality of the method's performance during an analysis is still imperative, and these obstacles must be overcome with analytically sound ingenuity and thorough documentation.

Commercial immunoassays and commercial thin-layer chromatography kits are provided with control materials specifically designed to be used for their intended purpose. These control materials are manufactured in bulk under strict quality control and are conveniently provided with the expected value, acceptable limits of variation, lot number, and expiration dates. However, it is good laboratory practice, where practical, to include at least one independently prepared positive control.

Control materials may be obtained from commercially available sources, although the cost can be high, especially if this is to be done for the very wide range of drugs typically analyzed by a typical post-mortem toxicology laboratory. These are usually supplied in the form of urine or lyophilized serum or plasma, with target concentrations, lot numbers, and expiration dates. Their stability may be short (5 to 30 days) once they have been reconstituted, but they remain stable for months if refrigerated in their lyophilized state. The drug selection available usually incorporates common drugs of abuse and of clinical therapeutic interest, which, albeit adequate, leaves the forensic laboratory with unaddressed needs. The matrices of these materials may not appropriately simulate the typical forensic sample under specific analytical conditions. Therefore, the suitability of these commercial control materials must be ascertained by evaluating them against properly selected calibrators under controlled conditions.

A reasonable source of control material is the pooling of excess laboratory specimens. This source is not very dependable, however, because of difficulties in obtaining unique drug selectivity, the uncontrolled degradation of biological fluids and drugs, biohazards, and increasing legal concerns regarding the use of human fluids and tissues for purposes other than strict determination of cause and manner of death of the individual from whom the specimens were collected.

An alternative is the preparation of controls in the laboratory using outdated whole blood or plasma from blood banks, voided urine, and tissue homogenates prepared from drug free sources. Some analysts in the field have successfully used bovine blood after adjusting the hematocrit to simulate human levels by diluting with water.¹⁶ The only concern about "homemade" controls is that there is no independent way of qualifying the process. For this reason, every effort should be made to ensure the quality of reference material, the proper maintenance of volumetric implements and balances, and the execution of good analytical skills in the preparation of the in-house control.

The process begins with the preparation of a stock solution from a certified reference drug material. This stock solution must be distinct from the one used to prepare the calibrators. It is axiomatic that if the same reference solution is used to prepare both, the control is invalid. A water-soluble organic solvent that readily dissolves the drug material without adverse reaction is the solvent of choice. Solvents that are not water soluble can be used, but they require additional steps to remove the solvent when further dilutions are made into aqueous biological fluids. A concentration of 1 mg of the un-ionized form of the drug per milliliter of solvent is convenient and adequate for most drugs analyzed. The solutions stored in capped amber vials at -20°C can have long shelf lives if care is taken to allow the solutions to reach room temperature before opening, thus avoiding moisture condensation in the solution. The stability of these solutions should be established periodically as described earlier in this chapter.

A decision must be made whether to prepare batches of control material for future use or to prepare a working stock solution from which fresh controls can be fashioned at the time of analysis. The decision to prepare large batches of control material for future use rests on the requirements that (1) the drug be stable for a reasonable period of time in the appropriately preserved matrix of choice, and (2) the control be used frequently enough to merit the effort of establishing the limits of variation for the batch. For example, assays that are used frequently, such as blood ethanol, are

good candidates for this type of control material. An assay that is performed about two or three times a year does not merit a batch preparation, even if the control material is deemed stable for a period of years in a frozen state.

A batch is simply prepared by making a proper dilution of the stock solution into the desired volume of biological fluid and adding the required preservatives as outlined in the procedures manual for the specimens being simulated. The control material can be dispensed into labeled vials containing working aliquots and stored until needed under the same protocols used for samples.

Control materials fashioned at the time of analysis are preferred for many post-mortem toxicology analyses. They are prepared fresh at the time of analysis by spiking an aliquot of a working stock solution into the required amount of blank matrix. Hence, any fluid or tissue homogenate can be fortified with the control before processing, allowing the performance of the assay to be monitored for any tissue. The working stock solutions may remain stable for long periods of time because they are prepared in organic solvents. Therefore, a single working stock solution may be used repeatedly to monitor performance even for infrequently performed analyses. However, precautions must be taken to prevent or minimize evaporation of the solvent.

The working stock solution is prepared by diluting the stock solution to an intermediate concentration so that a small aliquot added to the required amount of blank matrix yields the desired control concentration. The solvent used must be water soluble and care must be taken that the volume of control solution chosen to spike the blank does not affect the matrix significantly. Keeping the solvent concentration of the matrix well below 10% is advisable to avoid protein precipitation.

Once a control material has been procured, it is identified with a lot number and, if applicable, an expiration date. Using control materials, the assay is evaluated to determine accuracy and precision expressed as standard deviation and coefficient of variation, which are evaluated by standard statistical methods. Where practical, this requires that the control be analyzed 20 to 30 times over a period of several days by all analysts who perform the assay using the variety of measuring devices that could conceivably be used to perform the assay. A smaller number of analyses may be more practical where the analyte is not routinely performed.

Occasionally, the forensic laboratory needs to perform a rare analysis for which a control has not been established (e.g., yohimbine, estazolam) or one for which a control is impractical to maintain (e.g., toluene, cyanide). In these situations, one can perform a "spike recovery" study to verify that the calculated result was not influenced by matrix differences between the specimen and the calibrators. This is accomplished by spiking a replicate of the specimen with one of the working stock calibrator solutions. The solution is chosen so that the amount added is not less than one tenth the existing concentration, nor more than ten times the existing concentration, and that the addition does not produce a concentration higher than the limits of linearity. The spiked sample is analyzed and the result is used to calculate the percent recovery as follows.

Recoveries that are outside the 20% margin allowed by this principle indicate that matrix effects are abnormally high and that the original concentration calculated for the specimen is inaccurate. If this is the case, the method of additions discussed in Section 12.5.6.1.6 can be pursued in the quest for an accurate result.

12.5.7 Samples and Sampling

Sampling is often called the basis of analysis because the analytical result is never better than the sample from which it is derived. The purpose of sampling is to provide the analyst with a representative part of the "object" that is suitable for the analysis. In forensic work, an appreciation of how the analytes may decompose and how contaminants may be introduced are important factors to consider.^{17,18} The subject of samples and sampling is discussed in Chapter 12.2. The subject of safe handling of infectious materials has been treated in detail elsewhere.¹⁹

12.5.8 Analytical Methods and Procedures

The analytical method is the set of instructions detailing the entire procedure by which a particular analysis is performed. The instructions describe the preparation of reagents, standards, controls, and sample; the steps to isolate and concentrate the analyte; the instrumental requirements; and the data manipulation. It is in the execution of the method that most of the sources of error are introduced, so strict guidelines must be followed to control them.

12.5.8.1 Quality of an Analytical Procedure

An analytical challenge is approached by selecting the method that is most appropriate in terms of its quality features to tackle the chemical problem. The factors that govern the quality of an analytical procedure are the limit of detection, sensitivity, dynamic linear range, precision, accuracy, and selectivity. An in-depth discussion on the subject of quality of analytical procedures has been provided by Kateman and Pijpers.²⁰

Limit of Detection

The limit of detection can be defined as the smallest detector response given by the analyte that can be reliably differentiated from background noise produced by the instrument or the procedure. This signal is not necessarily quantifiable, since most detectors are not linear at low response levels.

The classical determination for the method detection limit involves statistical analysis of the probability that the signal is produced by the analyte, and not the instrument, with given confidence limits. These methods, which have been treated extensively in the literature, are involved and require that the background noise be consistent from sample to sample.^{21–23}

In methodologies that render irregular background noise from sample to sample it is commonly accepted to determine a signal-to-noise ratio of at least 3:1 to consider the signal as being produced by the analyte. Establishment of a higher signal-to-noise ratio as a decision guideline increases the confidence that the analyte is present at the expense of deciding it is absent at lower ratios. The benefit of doubt imparted to the decision at higher signal-to-noise ratios can be comforting from a forensic viewpoint.

Sensitivity and Linearity

The sensitivity of a method can be defined as the change in detector response given by a change in concentration. The detector response is composed of a part that depends on the concentration and a part that is independent of it (the blank). In addition, the detector response is not linearly proportional to the concentration over the entire range of possible values. The range of values for which the sensitivity is constant is called the “linear dynamic range,” and methods should be developed so that this range is as large as possible.

The linear dynamic range, or linearity, is limited at the lower level by concentration values whose detector response cannot be distinguished from the detector noise, or by ambiguous values of sensitivity. The linear range is limited at the upper level by saturation of the detector signal.

Precision

Precision is a measure of the dispersion of results when an analytical procedure is repeated on one sample. Although the dispersion of results may be caused by many sources, it is usually implied that it is caused by random fluctuations in the procedure. If no bias exists, the results usually scatter around the expected value in a normal distribution, described by a Gaussian curve (Figure 12.5.3).

Figure 12.5.3 Gaussian curve.

The normal distribution of the population of results is characterized by the position of the mean (x), and the standard deviation (s). The precision of an analytical method is often expressed as the standard deviation or coefficient of variation (CV), and it is calculated and monitored by analysis of control materials (Section 12.5.6.3).

Accuracy

Although the concept of accuracy is vague and difficult to interpret, it has been defined as the difference (error or bias) between an individual result, or the mean of a set of results, and the value that is accepted as the true or correct value for the quantity measured.²⁴

An accurate measurement is one that is free of bias, does not scatter when repeated, and results in the “true value.” The true value, however, is unknown because it must be measured, and measurements are biased and imprecise. Nevertheless, the accuracy can be estimated by measuring properties that are related to the concept of “accurate.” Precision can be measured and bias can be estimated. Youden²⁵ stated that the mean of the results obtained by a number of independent laboratories, using comparable methods of data presentation and data handling, can be assumed to be the “true value.”

Selectivity and Specificity

Selectivity refers to the ability of an analytical procedure to produce correct results for various components of a mixture without any mutual interference among the components. Specificity refers to the ability of an analytical procedure to discriminate between components in a mixture by their ability to produce a detector signal.

12.5.8.2 Qualitative Methods

Qualitative methods characterize the sample in terms of the identity of its toxic constituents. The identity can be specific, as produced by mass or infrared spectra, or nonspecific, as produced by immunoassays and spot tests.

Qualitative methods require that all analytes that can be detected or ruled out in the analysis be known. For nonspecific assays, such as thin-layer or gas chromatography, this can be an ever increasing list as new drugs are introduced.

With each assay, a negative control and a control representative of the analytes being tested should be analyzed. The positive control should contain the analytes near their respective limit of detection, and both should be prepared in a matrix similar to the samples. Interferences that can adversely affect the result should be indicated in the written procedure.

12.5.8.3 Quantitative Methods

Quantitative methods characterize the sample in terms of the quantity of its toxic constituents. The measured quantity carries with it an inherent uncertainty that must be known in order to appraise its reliability. The accepted thresholds of uncertainty, or limits of variation, are determined by quantifying the factors that affect the quality of the method. Therefore, each quantitative technique must be validated by determining its limit of detection, dynamic linear range, precision, and accuracy.

12.5.8.4 Method Development and Validation

Guidelines for method development instituted in a comprehensive procedures manual provide an effective way to tackle the analytical challenges that are frequently encountered in the forensic laboratory. The considerations listed below provide the basis upon which an analytical method can be implemented:

- Establishment of the intended purpose of the method
- Identification of chemical problems that must be addressed to fulfill the intended purpose of the method
- Search of the literature for existing methods that can fulfill the intended purpose and be accommodated by the laboratory

Appendix IC provides literature sources for qualitative and quantitative assay procedures for most common drugs. The references should serve as a starting point for method development.

Once the basic characteristics of the method have been established, the method is developed by evaluating and documenting as much of the following information as possible:

- Analytical principle of the assay
- Brief description of toxic substances being analyzed
- Sample preparation requirements
- The sources of materials and the preparation of reagents, standards, and controls
- Quantitative statements about the stability of the reagents, standards, and controls
- Procedural steps to isolate and/or concentrate the analytes
- Instrumental requirements and settings
- Validation parameters; limit of detection and/or quantification, linear range, coefficient of variation, and recovery efficiency
- Interferences
- Data handling
- References to the source of the method

All analyses should be performed by the procedures set forth in the procedures manual, and carried out explicitly as described by the procedure whenever possible. Exceptions should be made only when special considerations are dictated by the character of the specimen (for example, interferences resulting from multidrug content). When modification to a method is necessary, the exercise of good analytical judgment and proper documentation are essential to impart confidence in the result.

12.5.9 Instruments

In analytical chemistry, information about the chemical composition of a sample is obtained by measuring some chemical or physical property that is characteristic of the component of interest. These measurements are made by various analytical instruments designed to measure specific properties.

To apply instrumentation most efficiently to the problems, the analyst must understand the fundamental relations of chemical species to their physical and chemical properties. The analyst must know the scope, applicability, and limitations of physical property measurement with respect to qualitative and quantitative analysis. Knowing this, the analyst can call upon the instrumentation for the measurement of the desired properties with the needed accuracy and precision.^{26,27}

The instrument is a device that converts chemical information to a form that is more readily observable. It accomplishes this function in several steps that may include (1) generation of a signal, (2) transduction (transformation of the signal to one of a different nature, such as electrical), (3) amplification of the transformed signal, and (4) presentation of the signal by a scale, recorder, integrator, or printout. Some instruments also prepare the sample to a form that can be analyzed or perform separation of components for increased specificity. It is common to find a combination of instruments working in tandem to produce the desired results.

To ensure that the instrumental data are reliable, steps must be taken to control the proper function of the instrument. This can be accomplished by establishing standard operating procedures that address proper installation guidelines, a preventive maintenance program, periodic performance evaluations, and preanalysis checklists.

All documentation concerning instrument maintenance and checks should be kept in bound notebooks specific to each instrument. These are to be kept near the instrument for easy access and inspection by all analysts. With time, a history of the instrument will develop that will impart a great insight for effective and timely troubleshooting.

12.5.9.1 Installation

An effort should be made to install the instrument in a manner that is commensurate with the recommendations of the manufacturer. These usually include environmental, energy, and safety requirements that are necessary for the proper function and longevity of the instrument.

12.5.9.2 Preventive Maintenance

A preventive maintenance program can reduce the frequency of instrument failure during analysis. It also reduces the likelihood of major breakdowns and extended downtime. Preventive maintenance requirements and procedures are usually specified in the instrument operation manual. The time interval required between preventive maintenance services is dictated by the amount of use and environmental factors. Therefore, laboratories must establish their own protocols according to their needs.

12.5.9.3 Pre-Analysis Checklist

A review of vital instrument parameters before processing samples assures that the correct settings have been chosen for the analysis and that the instrument is in good working order. This becomes especially important when the instrument is used for multiple procedures by multiple analysts. Use of a checklist is the most effective way to ensure that no parameter is overlooked and produces documentation that pre-analysis checks were performed. The specific parameters to be checked and their proper settings will vary with the instrument.

12.5.10 Data

The American Academy of Forensic Sciences and the Society of Forensic Toxicologists recommend that before results are reported, each batch of analytical data should be reviewed by scientific personnel who are experienced with the analytical protocols used in the laboratory.¹ At a minimum this review should include chain of custody data, validity of analytical data and calculations, and quality control data. The review should be documented within the analytical record.

12.5.10.1 Chain-of-Custody Data

Review of the chain-of-custody documentation ensures that the analytical result represents the correct sample. The data necessary to accomplish this task include the dates and identification of individuals performing the sample collection and transportation to the laboratory; receipt; transfer of specimens or aliquots within the laboratory; chemical analysis; and analytical report.

12.5.10.2 Analytical Data

The first task of an analyst who wants to evaluate a procedure is to collect relevant data of measurements using that procedure. The second task is to reduce the number of measurements, remove irrelevant and erroneous data, and convert the measurements into statements pertaining to the condition of the procedure under control. To convert the data into a form that can be handled, data reduction procedures are applied.

Analytical instruments are usually equipped with data filters or data handlers that smooth and reduce the data collected, relieving the analyst of such arduous tasks. For this reason, the concepts of data production, information theory, data reduction, data handling, analysis of variance, pattern recognition, and system optimization are not discussed in this chapter. However, the analyst should have some understanding of how instruments perform data analysis. This knowledge will help the analyst identify corrupt data, correctly set thresholds for proper peak integration, and determine signal-to-noise ratios. A thorough discussion on data production and data reduction has been presented by Kateman and Pijpers.²⁸

A thorough review by responsible supervisory personnel of the raw analytical data and the calculations derived therefrom should be performed before a report is issued.

12.5.10.3 Quality Control Data

A review of the results obtained from the analysis of control material is essential to evaluate the performance of the analysis. This is accomplished by deriving control charts for each control material so that control rules or decision criteria can be applied to determine whether the method performed within expected limits of variation.^{29–32}

The control chart is a graphical representation of the arithmetic mean and the control limits calculated for the control material as described in Section 12.5.6.3. The x -axis is scaled to provide appropriate time period intervals. Horizontal lines are drawn corresponding to the mean (center) and multiples of the standard deviation above and below the mean, as shown in Figure 12.5.4. These graphs are sometimes referred to as Shewhart or Levey–Jennings charts.

The control rules or criteria described here are based on statistical properties arising from single control measurements, rather than replicate measurements, since they are more common. They provide a low level of false rejection, improved capability for detecting analytical errors, and some indication of the error type to aid in problem solving. Rejection of an analytical run occurs when the control value obtained violates one or more of the following rules, symbolized for brevity and convenience:

The proficiency program provides laboratories with chemically fortified samples simulating those encountered routinely by the laboratory for analysis. The program derives statistical data on the results reported by the participating laboratories and issues a summary of useful information about the results. When the result of a chemical analysis is compared to the results obtained by other laboratories on the same sample, the laboratory can make a responsible determination of the strengths and weaknesses of its overall operation. This information can be used to focus resources on those areas that need improvement, be it personnel, training, equipment, method development, reference materials, or the like. It also builds confidence in the methods that yield reliable results.

Forensic toxicology laboratories must participate in external proficiency testing programs that evaluate as many of the analytical tests in as many specimen types as possible. These programs are the only independent way to evaluate the reliability of the methods used and the overall operating procedures of the laboratory.

12.5.13 Accreditation Programs

Accreditation is playing an increasing role in the quality of work performed in forensic laboratories. It ensures that the laboratory has acceptable analytical methods, general procedures, and most important, that the standard operating procedures are followed. There are currently four organizations that offer accreditation in the field of forensic toxicology. The National Laboratory Certification Program (NLCP) is operated under private contract through the U.S. Substance Abuse and Mental Health Services Administration (SAMHSA).³³ That NLCP program applies only to U.S. federally regulated testing in the specific area of forensic urine drug testing for amphetamine and methamphetamine, cannabinoids, codeine and morphine, cocaine, and phencyclidine. The College of American Pathologists also operates a voluntary program for forensic urine drugs testing, but which covers a slightly greater range of drugs of abuse in urine.³⁴ However, the two major, broad-based accreditation programs that encompass forensic toxicology are run by the American Society of Crime Laboratory Directors Laboratory Accreditation Board (ASCLD/LAB), and the American Board of Forensic Toxicology (ABFT).^{35,36} The ASCLD/LAB program covers all aspects of forensic laboratory management and operation, including forensic toxicology, whereas the ABFT program is focused on forensic toxicology, and specifically those laboratories performing post-mortem toxicology and human performance drug testing (e.g., driving under the influence of drugs).

12.6 INTERPRETATION OF POST-MORTEM DRUG LEVELS

Graham R. Jones, Ph.D., DABFT

Office of the Chief Medical Examiner, Edmonton, Alberta, Canada

12.6.1 Introduction

In the early to mid-1900s, the practice of forensic toxicology was relatively limited in scope. Certainly, toxicologists could determine blood alcohol and a limited number of drugs with accuracy approaching that of today. However, the toxicological investigation was different in at least two respects. First, the sophistication of testing for drugs was limited, primarily relying on the efficiency of extraction techniques, followed by gravimetric and later spectrophotometric analysis. Second, with the exception of alcohol and a relatively limited number of drugs or poisons (e.g., salicylate, barbiturates, arsenic, heavy metals), there was a very limited database of reference drug concentrations available. The interpretation of quantitative results relied very heavily on the history and circumstances of the case, including the police investigation, witness accounts, and autopsy findings.

The development of gas chromatography (GC) and high-performance liquid chromatography (HPLC) during the early 1970s had a major influence on the development and growth of pharmacokinetics and therapeutic drug monitoring. As a result, the kinetics of drug absorption, distribution, metabolism, and excretion in clinical patients was easier to understand and predict. This coincided with a vast increase in the range of pure pharmaceuticals available, many of which were of lower absolute dosage compared with those previously available; for example, the replacement of barbiturates with low-dose benzodiazepines. It was logical that toxicologists started to use the pharmacokinetic data gained from living patients to interpret post-mortem blood concentrations, for example, to predict whether a given blood drug concentration was “in the therapeutic range,” whether the blood level was “fatal,” or even to predict the amount ingested prior to death. Experience has since shown that post-mortem drug concentrations must be interpreted from a perspective very different from for those in living patients. Many processes occur after death that can change drug and alcohol concentrations, sometimes to a very large extent.

The period of enthusiasm in the late 1970s and 1980s has given way to the realization that there are many unique aspects of post-mortem toxicology that must be considered when interpreting analytical results. It is no longer acceptable to interpret post-mortem toxicology results from tables of so-called therapeutic, toxic, and fatal ranges, without taking into consideration the medical history, the immediate circumstances of the death, and the various processes that can affect drug concentrations both before and after death. It is probably fair to say that many toxicologists and pathologists are less confident about interpreting post-mortem drug concentrations today — and with good reason — than they may have been 10 to 20 years ago.

It is important to remember that there are no “absolute” rules for the interpretation of toxicology results. The more information that is available to, and considered by the interpreter, the more likely are the conclusions reached to be accurate. In the courtroom, lawyers, judges, and jurors often view all science, including the forensic subspecialties, in absolute terms. Certainly, if the toxicologist does his or her job properly, the laboratory findings will have the required accuracy. However, the subsequent interpretation is in part based on the scope of the toxicology testing (not least including the range of specimens tested), in part on the quantitative results, and perhaps most importantly, on the history and circumstances surrounding the death. Attempts to interpret toxicology findings solely on the basis of so-called normal or reference ranges are irresponsible.

It is not the purpose of this chapter to teach anyone *how* to interpret post-mortem drug concentrations, but rather to outline some of the pre-mortem and post-mortem factors that should be taken into account when doing so.

12.6.2 General Considerations

12.6.2.1 The Analytical Result

It should be obvious that the interpretation of any toxicology test result will be no more reliable than the analytical result itself. The interpreter must be satisfied that the analysis is sufficiently accurate for the purpose, or at least know the limitations of the testing. Was the standard material used to prepare the calibrators pure and correctly identified? For example, was the salt or water of crystallization properly taken into account? Was the calibration properly prepared and valid in the range where the specimens were measured? Was the assay adequately verified by quality control samples? Was the assay sufficiently specific? Could endogenous substances or other drugs or metabolites have interfered with analysis of the specimen, either by obscuring the target analyte or by increasing the apparent concentration? If the specimen was analyzed only once, what was the potential for accidental contamination? Was there a matrix effect? For example, was recovery of the drug from the specimen the same, relatively, as from the calibrators? Using similar matrix calibrators (e.g., blood) is not necessarily a guarantee of that since post-mortem blood, by its nature, is variable from case to case, or even from site to site within the same cadaver. The extraction efficiency of drug or metabolite or internal standard from animal or outdated blood bank blood may sometimes be markedly different from decomposed case blood. Although it is practically impossible to know the “absolute” or true concentration of drug in a post-mortem specimen, the degree of confidence increases with the specificity of the analysis, with replication, or in some cases by applying multiple analytical methods of different physical or chemical principle.

The use of GC/mass spectrometry with multiple ion monitoring and stable isotope (e.g., deuterated) labeled internal standards will usually provide a higher degree of confidence in the accuracy of the analytical result, than, say, use of an immunoassay procedure. The completeness of the analysis should also be considered. It is never possible to test for every single drug during routine screening tests. However, a careful review of the medications or other potential poisons available to the deceased should assist the laboratory in determining whether any of these substances would have been detected if present in significant concentrations.

12.6.2.2 Post-Mortem Specimens

Relying on a toxicology result from a single specimen can be misleading, because of the post-mortem changes that can occur. The most commonly used specimen, blood, is not a homogeneous fluid. It is good forensic practice to have multiple specimens available, or at least blood specimens from different sites in the body, because of the potential difficulties in interpreting post-mortem toxicology results.

Blood

The concentrations of many drugs are affected by post-mortem redistribution through the vascular system from the major organs, by direct post-mortem diffusion from organ to organ, and sometimes by incomplete distribution. Sedimentation of blood after death may also affect the drug “blood” concentration obtained. For some drugs the distribution between blood and plasma is markedly uneven during life. However, toxicologists should be cautious about applying factors to “correct” for blood:plasma distribution unless it is known that the distribution is maintained after death. It

may be found that the blood:plasma distribution that exists during life, due to active processes, decays after death occurs, for example, due to changes in pH and, therefore, protein binding.

Toxicologists should be cautious about inferring the exact source of a blood specimen from the labeled description. Blood, simply labeled as such, could come from almost anywhere, even collected as pooled blood at the scene. Most toxicologists and pathologists are well acquainted with the widely discouraged practice of drawing blood by a “blind stick” through the chest wall. Although such blood may be labeled as “heart blood,” it may contain pericardial fluid, or worse, may be from the pleural cavity, and therefore potentially be contaminated by gastric contents, particularly if the death was traumatic or decomposition severe.¹ Even blood drawn from the “heart” after opening the body cavity at autopsy may contain blood from a number of sources. So-called “heart” blood may contain blood from one or more of the cardiac chambers — the ventricles and atria. However, it may equally contain blood that has drained from the pulmonary vein and artery (and hence the lungs), from the inferior vena cava (and hence from the liver), and from the aorta and subclavian veins. As a result, so-called heart blood is potentially one of the most nonhomogeneous specimens in the body. As described later, post-mortem redistribution and other factors can cause the concentrations of many drugs to vary markedly from site to site.^{2–4} Even drug concentrations in blood drawn from the same site, but simply placed into different collection vials, can also sometimes differ by severalfold.

It is generally recommended that to avoid the effects of post-mortem redistribution or diffusion from the major organs, femoral blood should be sampled wherever possible. While this is certainly a good practice, interpreters should be cautioned that there is no such thing as “pure femoral blood”; it is simply blood drawn from the site of the femoral vein. Certainly, if the proximal part of the femoral vein is ligated prior to sampling, it is likely that much of the blood will be “peripheral” and therefore relatively uncontaminated by blood from the major organs. However, this is rarely the case. Femoral blood is typically drawn by a “stick” to the unligated femoral vein in the groin area, such that blood will be drawn from above and below the site of sampling. If the volume drawn is relatively small (e.g., 2 to 5 mL), it is unlikely that much blood will be drawn down from the central body cavity. However, with some skill, it is often possible to draw 50 mL or more of blood from a “femoral stick.” Even with a limited knowledge of anatomy, it does not require much thought to realize that at least some of this blood will have been drawn down from the inferior vena cava, and hence from the liver. An alternative sampling technique is to cut the iliac vein at the side of the pelvis during autopsy, and only sample blood that is massaged out from the femoral vein directly into a test tube. Even if such a procedure ensures that the collected blood is from the femoral vein, some post-mortem changes may just as well have happened in this blood, too, e.g., diffusion from vessel walls and skeletal muscle. Since blood concentrations of some drugs have the potential for marked post-mortem change, it is good practice to analyze blood obtained from more than one site, plus tissue or other specimens where this may be useful.

Vitreous Humor

Vitreous humor, although limited in volume (e.g., 3 to 6 mL), is an extremely useful specimen. It has been used for years to verify post-mortem blood concentrations of ethanol, since post-mortem fermentation does not occur to any significant extent in the eye. However, vitreous humor has also been useful for a number of drugs. For example, it is well known that digoxin concentrations will rise after death in cardiac blood, due to post-mortem redistribution from myocardial tissue, and possibly other organs. Consequently, vitreous digoxin concentrations are more likely to reflect those in ante-mortem plasma.⁵ Vitreous humor has been used to analyze a large number of other drugs, including barbiturates, cocaine, morphine, tricyclic antidepressants, and benzodiazepines.^{6–10} However, interpretation of vitreous drug concentrations is difficult, in part because very few studies have been published that relate blood concentrations to those in vitreous humor, and in part because the large *ad hoc* data on vitreous drug concentrations is fragmented in innumerable case reports.

In general, however, those drugs that tend to be somewhat hydrophilic at physiological pH (e.g., digoxin, benzoylcegonine, acetaminophen, salicylate) are more likely to have concentrations approaching those in blood or plasma, than those drugs that are either highly protein bound (e.g., tricyclic antidepressants) or highly lipophilic (e.g., benzodiazepines). In fact, a significant negative correlation between the vitreous:blood concentration ratio and the degree of protein binding of different drugs has been reported.¹¹

Because the eye is remote from the central body cavity and the abdominal organs, it has been suggested that vitreous may be a useful fluid for the determination of drugs that are subject to post-mortem redistribution. That may hold true for many drugs such as digoxin. However, others have shown that some drugs, notably cocaine, may increase in concentration in the vitreous humor after death.⁹ Post-mortem diffusion of drugs to the vitreous from the brain, particularly in bodies lying in a prone position for an extended time, may be a possible source of error, and warrants systematic studies.

Liver

Many toxicologists rank the liver second only after blood in importance as a specimen of interpretive value in post-mortem toxicology. It is particularly valuable for the tricyclic antidepressants and many other drugs that are very highly protein bound. It is useful for the phenothiazine neuroleptics which have a very large dosage range, and hence range in “therapeutic” blood concentrations. Liver tissue is also of value for interpreting post-mortem concentrations of many other drugs where a sufficiently large database has been established, and particularly where blood is not available due to severe decomposition, fire, or exsanguination.

One other aspect of liver drug concentrations should be considered. It is known that post-mortem diffusion from the stomach may artifactually elevate concentrations of the drug proximal to the stomach — for example, after an overdose, where both the concentration and absolute amount of drug in the stomach are high.^{12,13} However, little appears to have been done to assess the kinetics of drugs in the liver after therapeutic doses. For example, common sense would suggest that drug concentrations in the liver, and particularly those that are strongly protein bound, would increase dramatically in the period after a dose was taken, compared with that at steady state. This might be particularly important for drugs with a relatively long half-life and that are often taken in single nighttime doses, or divided with a large portion of the dose at night. As for other specimens, liver concentrations are extremely valuable for assessing the role of many drugs in a death, but only in conjunction with other analytical findings and history.

Gastric Contents

Interpretation of the analytical findings of drugs in the gastric contents is largely dictated by common sense. It is the *amount* of drug or poison remaining in the gastric contents that is important; the concentration of the drug is generally of far less importance. The tricyclic antidepressants offer a good example. Most forensic toxicologists regard total tricyclic concentrations greater than 2 to 3 mg/L, even in post-mortem “cardiac” blood, as at least potentially toxic or fatal. So what does a gastric tricyclic concentration of 1500 mg/L mean? The answer is, on its own, not much, except that the person may have consumed his or her medication a relatively short period prior to death. For example, 200 mg amitriptyline at night is a fairly common dosage. If the gastric volume was, say, 120 mL, then 1500 mg/L would be completely consistent with the person taking the normal dosage just prior to death — probably from unrelated causes. However, if in our example the gastric volume at autopsy was 900 mL, then a concentration of 1500 mg/L would calculate out to 1350 mg/900 mL in the stomach, and therefore almost certainly consistent with an overdose.

Conversely, a relatively low absolute amount of drug in the gastric contents, with or without a high concentration, does not rule out the possibility of an overdose. Numerous case histories have

shown that it may take several hours for an individual to die from an intentional overdose, depending on the exact drugs or poisons ingested, the amounts, co-ingestion of alcohol, general state of health and age. It is not unusual for people to die from an oral overdose with less than a single therapeutic dose remaining in the stomach, notwithstanding the fact that an overdose of drugs can be irritant to the stomach lining and therefore delay gastric emptying. Extensive vomiting before death can also reduce the amount of drug remaining in the stomach at the time death occurs.

Two other aspects of “gastric toxicology” should be mentioned. The simple presence of a drug in the gastric contents does not necessarily mean that the drug was recently consumed, or even prove that the drug was taken orally. Most drugs will be re-excreted into the gastric contents through the gastric juice, maintaining an equilibrium between the gastric fluid and the blood. This is especially so for drugs that are basic (alkaline) in nature. This can readily be demonstrated where it is known that a drug has only been administered intravenously under controlled conditions, and yet can be found later in small concentrations in the gastric contents. The same phenomenon can be seen with drug metabolites where, invariably, concentrations can be found in the gastric fluid. While it could be argued that microbial metabolism could have occurred in the stomach, it is more likely that the majority of the metabolites found were secreted into the stomach via the gastric juice. Conversely, the presence of “ghost” tablets in gastric contents has been reported for at least one type of slow-release analgesic, where overdose or abuse was not suspected. Apparently, the wax-resin matrix of these sustained release tablets may remain in the gastric contents long after the active ingredient has diffused out.¹⁴

More commonly, significant amounts of conglomerated, unabsorbed tablet or capsule residue can be found in the stomach many hours, or even a day or two after a large overdose was consumed. These masses can occur after overdoses where large amounts of capsules or tablets may form a gelatinous mass, which is not readily dissolved or broken up, and which may lie slowly dissolving; they are called bezoars.¹⁵ While the term can apply to unabsorbed masses of almost anything (e.g., hair balls), it is also applied to unabsorbed drug formulations. They occur, at least in part, because gastric emptying time is delayed significantly by irritants, including large amounts of undissolved drug residue. However, the phenomenon is also occasionally seen in patients where overdosage is extremely unlikely (e.g., controlled setting such as a hospital or nursing home), but where several unabsorbed tablets may be recovered from the stomach. This is more likely to occur where enteric-coated tablets are involved, which do not dissolve in the stomach, but may stick together to form a small mass of tablets. It is also more likely to happen in elderly individuals, or in other patients where gastric motility is abnormally slow.

Urine

It is almost universally accepted that, with few exceptions, there is very little correlation between urine and blood drug concentrations, and even less correlation between urine drug concentrations and pharmacological effect. So many factors affect urine concentration, such as fluid intake, rate of metabolism, glomerular clearance, urine pH, and the times of voiding relative to the dose, that any attempt to predict or even estimate a blood concentration from a urine concentration is pure folly. As always there are some exceptions. Urine alcohol concentrations can be used to estimate the approximate blood alcohol concentration, but only if the bladder is completely voided and the measurement made on the second void. Estimates of the body burden of some heavy metals are still made on 24-h urine collections.

Brain

The brain is the primary site of action of many forensically important drugs, such as the antidepressants, benzodiazepines, and narcotics. It is potentially a very useful specimen for the measurement and interpretation of drugs because it is remote from the stomach and other major

organs in the body and would not be expected to be affected by post-mortem diffusion and redistribution. However, although drug concentration data in brain tissue are not hard to find in the literature, it is largely fragmented into innumerable case reports which seldom specify what anatomic region of brain tissue was analyzed. The brain is an anatomically diverse organ such that concentrations of many drugs vary significantly from one region to another — up to about twofold.^{2,4}

Other Soft Tissues

Most of the major organs such as the kidneys, lungs, spleen, and myocardial tissue have at some time been analyzed to estimate the degree of drug or poison exposure. However, for most drugs, adequate reference databases are not available in the literature, so the interpretive value of these measurements may be limited. Skeletal muscle has the potential to be one of the most useful specimens for drug or poison determination, particularly where the body is severely decomposed, or where post-mortem redistribution or diffusion might affect measurement in blood or other organs. The problem is one of obtaining sufficient reference values for that drug in skeletal muscle in order to make a confident interpretation. Some studies have been published, but data are scattered and incomplete.^{2,4,16}

The potential usefulness of bone marrow for the determination of both drugs and alcohol has been explored.^{17–19} For drugs and other poisons at least, this could be very useful in cases where severe decomposition, fire, or the action of wild animals has made the major organs unavailable, but where bone marrow can still be harvested and analyzed. As for many other specimens, the problem is again one of establishing an adequate and reliable database of reference values.

Other Fluids

Bile has been used for decades as one of the primary specimens analyzed in the forensic toxicology laboratory, but mainly for the detection and measurement of morphine. However, the usefulness of bile has decreased in the past few years as sensitive immunoassays and mass spectrometry based assays have been developed for whole blood. For most drugs, including morphine, the interpretive value of bile is limited. Biliary drug concentrations may also be influenced by post-mortem diffusion from the liver and the stomach.

Cerebrospinal fluid (CSF) is also a potentially useful specimen for the measurement and interpretation of drugs, since it is the fluid that “bathes” the central nervous system, the brain, and spinal cord. Its limitation lies mainly in the fact that it is often more difficult to collect than blood post-mortem, and as for many other specimens, there is a very limited database of reference values. As for the vitreous, drugs that are highly protein bound or those that are lipophilic will tend to have significantly lower concentrations than in the blood.

Injection Sites, Nasal Swabs

Suspect injection sites are periodically excised and submitted for analysis, to support evidence of that route of administration. Certainly, it is not difficult to perform such analyses. However, the simple qualitative detection or even quantitative measurement of a drug in a piece of skin is evidence only that the drug was taken or used, not that it was necessarily injected, let alone at that site. Sometimes it is forgotten that most drugs are distributed throughout the body from any route of administration, such that any piece of skin will contain some amount of the drug. For such measurements to be useful, a similar piece of skin from another part of the body, not suspected to be an injection site, must be analyzed for comparison. Only if the concentration in the suspect site is substantially higher than that in the reference site can meaningful conclusions be drawn. Even then, a perfect injection may not cause persistent elevated drug concentrations at the intravenous injection site, in contrast to an intramuscular or subcutaneous site. Similarly, the simple detection

of a drug such as cocaine in a nasal swab does not prove that the drug was “snorted.” Any fluid secreted by the body, including sweat, vaginal fluid, and nasal secretions, will contain some concentration of the drug. In this instance, quantitative determination is difficult and interpretation even more so unless the concentration of drug in the nasal secretions is extremely high relative to the blood.

Hair

Most drugs and poisons will be absorbed by bone, nails, and hair. Hair has long been used for the determination of arsenic and heavy metals, and by cutting the hair into sequential sections, for estimating the duration of exposure to the poison.²⁰ More recently, hair has been used for the determination of drugs of abuse in workplace and probation testing. Further, hair analysis can also be applied to estimate compliance in drug substitution programs and may also prove useful in therapeutic drug monitoring. In drug-facilitated crimes, the detection of a particular poison, such as GHB,²¹ zopiclone,²² and thiopental²³ in hair has been used to document the exposure in several drug-facilitated crimes, but a negative finding can usually not exclude an exposure.²⁴ Finally, hair analysis has the potential to be useful in post-mortem situations, for example, to estimate the duration of exposure to a drug or toxin, and hence provide information about the subject’s previous drug use.^{25–29}

The incorporation of drugs into hair is to a large extent due to melanin binding.³⁰ Hence, comparisons of levels between individuals is very risky. Even if the melanin content in the hair is measured, there are different types of melanin, and besides, a correction for total melanin content can only be applied to drugs where the drug-melanin binding characteristics have been firmly established. For most drugs, such information is lacking, and hence, the exact hair drug concentration per se is rarely informative.

Nails, Bone

One advantage of analysis of keratinized materials that should be emphasized is the stability of drugs in hair and nails, which means that such samples can be stored in room temperature for very long periods without major degradation of incorporated drugs. Drugs are incorporated into nails via both the root of the growing nail and via the nail bed.³¹ This implies that during the growth of the nail, drugs follow the movement of the keratinized matrix both upward and forward. In addition, the growth of nails is variable and generally slow. Hence, a temporal mapping of previous drug intake using analysis of nails is hardly possible. On the other hand, nails are almost always available for analysis, whereas hair is not; some subjects may present with alopecia totalis, or have shaved the hair on many body parts. Despite the limitations as to the growth rate of nails, this matrix has the potential to be a useful source for information about the drug use history of the decedent.

Most drugs and poisons will be taken up in bone and therefore, unless volatile, will be detectable in skeletonized remains. The interpretation of concentrations of certain drugs or poisons is relatively easy since either the normal or reference values are well established (e.g., arsenic; heavy metals), or the substance should not be present in any concentration (e.g., strychnine). However, interpretation of specific concentrations of pharmaceutical drugs or drugs of abuse is problematic because of limited reference levels. In addition, it should be recognized that bone is continuously remodeled; hence, drugs incorporated in bone tissue over time will be liberated and re-delivered to the blood. This means that a negative detection in bone does not rule out an exposure and a positive detection will not give very much information as to the time for exposure.

Paraphernalia: Syringes, Spoons, Glasses

Most forensic toxicologists are willing to analyze potentially drug-related exhibits found at the scene of death. Syringes or spoons can provide a valuable confirmation of drugs that may have

been used prior to death. For example, heroin is so rapidly broken down to morphine that little or no heroin, or even monoacetylmorphine, may be detectable in post-mortem blood. The finding of morphine in, for example, blood, could indicate either use of heroin or a morphine salt (or codeine, if it was also found). However, it should be borne in mind that most addicts reuse syringes and therefore the presence of a drug in a syringe found in the same room as a body does not necessarily mean that drugs contained therein were involved in the death, although it may provide circumstantial evidence. The use or abuse of insulin in a person without diabetes is exceptionally difficult to prove, since blood insulin concentrations are so variable, are difficult to determine accurately in post-mortem blood, and even during life correlate poorly with blood glucose. Insulin abuse is uncommon,^{32,33} but in those cases where it happens may be difficult to prove post-mortem without a good clinical history. However, detection of insulin in a used syringe near someone who was not prescribed the drug can provide useful circumstantial evidence of abuse. The presence of drug residues in drinking glasses or cups can provide evidence of at least the route of ingestion and in most cases assist with the determination of manner of death, especially if the drug residue is large and obvious. Care would obviously have to be taken to distinguish, say, a multiple drug overdose mixed in a glass of water, from two or three hypnotic tablets introduced into an alcoholic beverage for the purposes of administering a “Mickey Finn.”

12.6.3 Pharmacokinetics

Although other parts of this book deal with the topic of pharmacokinetics in some detail, it is worth reviewing the basics as it relates to post-mortem interpretation. The kinetics of all drugs and poisons in the body are characterized by absorption, distribution, metabolism, and excretion. All these parameters affect the concentrations that will be found in the body after death, and therefore interpretation of analytical toxicology results.

12.6.3.1 Absorption and Distribution

Absorption may be via the oral route, parenteral (e.g., intravenous, intramuscular, subcutaneous), pulmonary, dermal, and rarely, rectal. The route of absorption can be very important to the interpretation. For example, many drugs are extremely toxic via the intravenous route, especially if given rapidly. For example, heroin, barbiturates, and many other drugs can cause severe hypotension, and may be fatal, if given rapidly, even though the total dose given is within the range normally considered “therapeutic.” The resulting post-mortem blood concentrations may be below those normally considered fatal. At the other extreme, dermal absorption of medication is probably the slowest, such that even therapeutic concentrations in blood may take several hours to reach. Moreover, absorption of the drug may continue for several hours after the source of the drug, for example, a transdermal patch, is removed, due to the depot of medication which accumulates in the upper layers of the skin. In these circumstances the dose is difficult to control, and if toxicity occurs, it is important that the patient be monitored for several hours after the patch is removed, in case of continued toxicity.³⁴

Morphine provides a good and common example of why interpretation of blood concentrations alone in isolation from case history is difficult. First, opiate tolerance can vary tremendously between individuals and even within the same individual over a relatively short time span (days or weeks). Tolerance is an important consideration both clinically, where opiates may be chronically administered for pain, and in abuse situations where they are used for their euphoric effect. In clinical situations the issue of tolerance is complicated by the fact that patients in severe pain can tolerate higher doses of opioids than those in whom the pain is mild. It is also accepted that less opioid is required to prevent the recurrence of pain than to relieve it.³⁵ The form of the opioids will affect how rapidly the drug crosses the blood–brain barrier and, therefore, how potent it is. For example, heroin (diacetylmorphine) is at least twice as potent as morphine, probably because

it is more lipid soluble and reaches the central nervous system faster than the more hydrophilic drug, morphine. It has been suggested that heroin may simply be a pro-drug for morphine, but one that reaches the site of action more efficiently. As a result, blood concentrations of morphine seen in heroin abuse deaths are frequently lower than concentrations resulting from the therapeutic administration of oral or parenteral morphine in clinical situations. The situation is complicated further because morphine is extensively metabolized by conjugation with glucuronic acid.

Originally it was assumed that this resulted in exclusively water-soluble metabolites, which were pharmacologically inactive. However, while morphine-3-glucuronide is devoid of narcotic activity, morphine-6-glucuronide, which is typically present in blood at higher concentrations than unconjugated morphine, is more potent than morphine itself.^{36–38} Furthermore, much of the case data published in the clinical and forensic toxicology literature does not even distinguish between unconjugated and “total” morphine, let alone the 3- and 6-glucuronides, which are seldom measured routinely. With all these variables, it is no wonder unconjugated morphine blood concentrations correlate poorly with analgesic effect and central nervous system depression. A good example of this has been described where prolonged respiratory depression was observed in three patients in renal failure where morphine concentrations were extremely low, but where morphine-6-glucuronide had accumulated to toxic levels.³⁹

12.6.3.2 Metabolism and Pharmacogenetics

A detailed treatise on the mechanisms of drug metabolism and the accumulation of drugs or metabolites due to impaired metabolism is beyond the scope of this chapter. However, it is worth pointing out at least three different scenarios where impaired metabolism can have a significant impact on the interpretation of results. Metabolism can be impaired by liver disease, such as advanced cirrhosis. However, not all metabolic pathways will be impaired equally by liver disease, and indeed some pathways may be affected little, if at all. Oxidative pathways, which are easily saturable, are likely to be affected more than others, such as glucuronidation. A person's metabolism may be genetically deficient, for example, in cytochrome P4502D6 (CYP2D6). This pathway is responsible for many oxidative transformations such as ring hydroxylation of the tricyclic antidepressants, and genetically poor metabolizers can be identified post-mortem.⁴⁰ Third, co-ingested drugs can inhibit one or more drug metabolism pathways. For example, most or all of the selective serotonin-reuptake inhibitors (SSRIs) inhibit CYP2D6 and some are extremely potent in this regard. The degree of elevation of the drugs or metabolites affected depends very much on the respective dosages of the drugs involved and, not least, on the “metabolic reserve” of the individual patient. Some drug–drug interactions or genetic polymorphism may only result in slightly elevated drug or metabolite concentrations, perhaps necessitating lowering of dosage. However, in some circumstances the increases may be so dramatic as to cause life-threatening toxicity or death, particularly where the side effects were not sufficiently severe to alert the physician or patient that cardiotoxicity might be a problem. At least two cases involving probable impaired metabolism of imipramine have been described in the forensic literature.⁴¹

12.6.3.3 Calculation of Total Body Burden

Calculation of the total amount of drug ingested in self- or homicidal poisonings have been attempted many times over the years. This was attempted by the toxicologist who analyzed the remains found in the basement of Dr. Harvey Crippen, the renowned London poisoner who used hyoscine.⁴² Calculations typically involve measurement of the drug or poison in the major organs including, where possible, skeletal muscle, and then taking into account the organ weights to arrive at a total estimate of the amount in the body. In some cases, the amounts have correlated very well with the available physical evidence (e.g., amount of drug in an empty injection vial or amount prescribed).^{43,44} Doubtless, in some other examples attempted by toxicologists, correlation with the

physical evidence was less convincing, or not possible. In order for such calculations to be meaningful, a number of factors must be assumed.

Perhaps most important, the particular part of the tissue or blood sample analyzed must be representative of the remainder of the organ or tissue. Since most organs are not homogeneous and because uneven post-mortem diffusion (as discussed later) can lead to non-homogeneity of concentration, being sure of the average concentration of drug within any one organ may be difficult without analyzing that entire organ. While it is easy to know the weight of individual organs such as the heart, lungs, liver, kidneys, and brain, it is very difficult to reliably estimate the total amount of tissue into which most drugs readily distribute including the skeletal muscle. While the mass of skeletal muscle can be estimated from medical tables, given a person's height and weight, there is no assurance that the concentration of drug measured in one or two portions of skeletal muscle is representative of that in muscle from all other parts of the body.

Similar arguments apply to adipose tissue, where it is more difficult to obtain representative samples and accurately assay. It should also be borne in mind that for a person chronically taking a drug with a very large volume of distribution and long half-life, the equivalent of many times the total daily dose will be *normally* present in the body, even after therapeutic doses. Estimation of the total body burden of a drug may not be without value in all cases; it must be done with caution and the variables well understood and acknowledged. It is the rare cases of homicidal poisoning where significant weight may be erroneously placed on such calculations and where the stakes are the highest.

12.6.3.4 Estimation of Amount Ingested from Blood Levels

Given the foregoing discussion, it should go without saying that using pharmacokinetic calculations to try to estimate dosage, given a post-mortem blood concentration, is of virtually no value and can be extremely misleading. Several factors make such calculations invalid. The blood drug concentration measured post-mortem must be representative of that present at the time of death. As discussed elsewhere in this chapter, that is often not the case, and it is very difficult to predict whether any given post-mortem drug concentration represents the concentration at the time of death, even for drugs for which post-mortem redistribution is thought to be minimal. Any toxicologist who has routinely analyzed drugs in multiple blood samples from the same case knows how often those concentrations unexpectedly vary from sample to sample. Also, the drug must be at steady state at the time the person dies. By the very nature of drug-related deaths, that is rarely the case. Even if the gastric contents contain relatively little drug, much of the drug could still be present in the ileum, or at least not have attained equilibrium with muscle, adipose tissue, and the major organs. Finally, the rate of absorption, bioavailability, volume of distribution, half-life, rate of metabolism, and clearance are seldom known for any specific individual and can vary tremendously between subjects. The estimation of dose from post-mortem blood concentrations is a practice of the foolhardy.

12.6.4 Post-Mortem Redistribution and Other Changes

One question should be asked before attempting to interpret post-mortem drug concentrations: Is the concentration found likely to represent, at least approximately, that present at the time of death? Unfortunately, the answer is often a flat no, or at least not necessarily. A number of factors need to be considered.

12.6.4.1 Incomplete Distribution

It is often the case that sudden deaths involving drugs are caused by abuse or suicidal drug overdose. Death will therefore usually occur before steady state has been reached. If a person is actively absorbing an overdose, it is likely that the concentration of the drug in blood leaving the

liver (i.e., the inferior vena cava and right atrium) will have a somewhat higher concentration than, for example, venous blood returning from the peripheral vessels (e.g., femoral vein), for no other reason than a substantial amount of the drug will be absorbed during the course of circulation through the body. This has been demonstrated in living patients with concentration differences up to about twofold recorded between arterial and venous blood.^{45,46} It is an open question if this is a practical issue in post-mortem toxicology. In two cases of almost instantaneous death following heroin injection, the concentrations of morphine and codeine in blood collected from heart, brachial veins, and femoral veins were uniform, indicating a very rapid equilibrium.⁴⁷

12.6.4.2 *Post-Mortem Redistribution and Post-Mortem Diffusion*

Post-mortem redistribution and post-mortem diffusion involve the movement of drug after death along a concentration gradient. Although the differentiation of these terms is not always clear in the literature, post-mortem redistribution generally refers to the release of drugs from areas of higher concentration in organ tissues and subsequent diffusion into and through the capillaries and larger blood vessels of those organs. Post-mortem diffusion generally refers to the diffusion of drug along a concentration gradient, from an area of high concentration to an area of low concentration. The usual scenario is where a high concentration of drug in the stomach contents (e.g., after an overdose) causes elevated concentrations of the drug in nearby tissue (e.g., proximal lobe of the liver) or blood.

Much is still unknown about the extent to which post-mortem changes in drug concentration occur and the drugs affected; however, some generalizations can be made. Post-mortem redistribution is likely to be most marked for drugs that are highly protein bound, but particularly those sequestered in the major organs such as the lungs and liver (e.g., tricyclic antidepressants, propoxyphene, chloroquine). Post-mortem redistribution starts to occur within an hour after death and continues as the post-mortem interval increases. The most important quantitative changes in blood drug concentration occur within the first 24 h and are highly site dependent. In general, increases will be greater in blood from “central” sites, such as the vessels near the major organs, than in more peripheral sites, such as the femoral veins. However, blood drug concentrations can vary fivefold or more between cardiac, hepatic, and pulmonary sites.^{2,4} Given the very close proximity of these major vessels to one another and the organs they serve, it is impossible to even estimate peri-mortem drug concentrations based on the post-mortem interval and site from which a blood sample was drawn. Even aside from the unpredictable nature of post-mortem redistribution per se, blood from the “heart,” if labeled as such, could have come from either of the cardiac atria or ventricles, the pulmonary vein or artery, the aorta or the inferior vena cava.

Since it is known that many drug concentrations change after death, due to redistribution from the major organs, it is recommended, that post-mortem blood for drug and alcohol analysis be taken from a peripheral site such as the femoral vein. However, it should be emphasized that even if a “good” femoral blood sample is obtained, it is no guarantee that the drug concentrations subsequently measured will represent those present at the moment of death. In fact it is well established that femoral blood concentrations of many drugs can increase twofold or more after death. While it is possible that some of this increase is due to diffusion of released drug down the major vessels to the groin, it should be borne in mind that drug concentrations in skeletal muscle are often twofold or more higher than in the peri-mortem blood.^{2,4} Given the mass of muscle surrounding these relatively small peripheral vessels, diffusion of drug directly into the blood across the vessel wall is very likely to occur. While in many of the published studies on post-mortem redistribution the vessels have been carefully ligated prior to taking blood samples, this is rarely done during routine medicolegal autopsies. Consequently, blood labeled as “femoral” may contain blood drawn down from the inferior vena cava. This is particularly likely to be the case where large volumes (e.g., 30 to 50 mL) have been obtained from a supposedly femoral site. It should also be obvious that it does not matter whether the syringe needle is pointing down toward the leg!

The mechanisms for post-mortem redistribution probably involve release of drug from protein-bound sites after death occurs, with subsequent diffusion into interstitial fluid, through the capillaries and into the larger blood vessels. Since this process appears to start within an hour or so of death, decomposition or putrefaction *per se* is not likely to play a role, at least in the early stages. It is more likely that cessation of active cellular processes and the rapid fall in blood and tissue pH that occurs after death would lead to changes in the conformation of proteins and therefore release of some proportion of drugs present from the protein-bound state. It is important to bear in mind that these changes start well before putrefaction and microbiological action are likely to play a role.

Other types of post-mortem diffusion can occur. For example, it has been demonstrated that over a period of a day or more, significant changes in drug concentrations in the major organs can occur. This has been shown for the tricyclic antidepressants, where concentrations in the lungs tended to decrease, commensurate with an increase in concentration in the liver.⁴⁸ This study was done in such a manner as to show that these changes can occur due to direct diffusion from one organ to the other, independent of the residue of drug in the stomach. However, the magnitude of these changes is not likely to affect interpretation of tissue drug concentrations to a significant extent. It has also been demonstrated that post-mortem diffusion of drug from the stomach can markedly increase drug concentrations in proximal lobes of the liver and lungs, as well as post-mortem blood in some of the central vessels.^{12,13} Ironically, when organ tissue was analyzed in previous decades, post-mortem diffusion into the liver or lungs might have been less important since it was not uncommon to homogenize large amounts of organ tissue (e.g., 500 g), such that any local increases in concentration would be averaged out. However, today the tendency in many laboratories is to homogenize small amounts of tissue (e.g., 2 to 10 g), which could lead to a gross overestimation of the amount of drug in the organ if the sampled tissue was taken close to the stomach. The potential for post-mortem diffusion of drugs in this manner has been known for decades, but recent work has brought the issue the attention it deserves and better quantified the potential changes.

Aspiration of gastric contents can provide one more important mechanism whereby post-mortem blood concentrations can be artificially elevated.⁴⁹ This can occur agonally, as death is occurring, or after death, during transportation of the body. It is a factor that may more commonly occur after overdose where the stomach contains a very concentrated cocktail of one or more drugs, with or without alcohol. However, it could also be very important to consider in deaths where therapeutic doses have been consumed and death occurs as a result of unrelated natural causes. It is not uncommon, for example, for tricyclic antidepressants to be taken as a single nightly dose, and in fact large doses of many antipsychotic drugs are taken at night. This can result in drug concentrations in the stomach of the order of grams per liter, which if aspirated could result in significant increases in some local post-mortem blood concentrations. Not surprisingly, the pulmonary vein and artery blood concentrations are elevated to the greatest extent following simulated aspiration. This is more significant than it might seem because much of the so-called "heart blood," which is often sampled at autopsy, is in fact blood of pulmonary origin drawn from the major pulmonary vessels or the left atrium. A comprehensive discussion of the possible mechanisms for post-mortem redistribution has been published.⁵⁰

12.6.5 Other Considerations

12.6.5.1 Trauma

Severe trauma can affect the interpretation of both alcohol and drug concentrations. For example, it is not uncommon for severe motor vehicle accidents to result in rupture of the stomach and diaphragm. This can easily result in the release of gastric fluid into the body cavity. Because blood may be difficult to obtain from discrete vessels, pooled blood from the pleural cavity may be sampled. If an autopsy is performed, the origin and nature of the fluid so drawn should be

obvious, and hopefully noted. However, if an autopsy is not performed and “blood” is sampled through the chest wall in an attempt to obtain cardiac blood, the coroner or medical examiner may be unaware that the sample is contaminated with gastric fluid. If even small, therapeutic amounts of drug remain unabsorbed in the gastric contents in these circumstances, it can result in what appears to be a grossly elevated “blood” drug (or alcohol) concentration. The release of microorganisms from the gastrointestinal tract and subsequent potential for fermentation is a well-recognized problem.

Trauma causing extended blood loss may also affect blood drug levels, since the physiological reactions include, in addition to increased heart rate and peripheral vasoconstriction, plasma volume refill. Hence, blood levels may increase or drop, depending on their concentrations in the restoration fluid. Experimentally, codeine and morphine blood levels were found to increase significantly after controlled exsanguination in rats⁵¹ and a similar study showed that the analgesic effect of morphine was elevated when given to rats with hemorrhagic shock.⁵² Although further studies are needed to determine the impact of and conditions for such antemortem redistribution for several drugs with different pharmacokinetic properties, the phenomenon should be considered in trauma cases with longer duration of blood loss.

12.6.5.2 Artifacts of Medication Delivery

Artifacts of absorption and distribution must be recognized when interpreting post-mortem blood concentrations. For example, it is quite common to find grossly elevated concentrations of lidocaine in cases where resuscitation has been unsuccessfully attempted. Concentrations may be two to five times those normally considered therapeutic when lidocaine is given by intravenous infusion for the treatment of cardiac arrhythmias. If lidocaine is administered as a bolus intracardiac injection and normal cardiac rhythm never established, very high local concentrations will result in the cardiac blood. These could be interpreted as “fatal” unless all the circumstances are considered.

Devices that automatically deliver medication by the parenteral route can lead to artificially high blood concentrations post-mortem. Most of these devices will continue to periodically dispense medication, usually narcotics, into the vein after a person dies, unless they are switched off and disconnected quickly. This can result in extremely high local concentrations of drug, which may be misinterpreted as an overdose.

Transdermal patches left on a body after death will give rise to locally high concentrations of the drug (e.g., fentanyl). Since these patches rely primarily on passive diffusion across a rate-limiting membrane for drug delivery, the concentration of the medication in the local area will continue to rise after death, albeit at a slower rate. Since blood circulation through the skin obviously stops after death, the drug will no longer be transported away except by diffusion, allowing a local build-up of drug. However, such a high concentration gradient exists between the gel containing the medication in the patch and the skin, that even modest post-mortem diffusion might be expected to raise the post-mortem blood and tissue concentrations up to several inches away.

12.6.5.3 Additive and Synergistic Toxicity

When interpreting drug concentrations it is important to take into account the sum of the effects of all of the drugs detected. This is often an issue in drug abuse deaths, particularly those involving prescription drugs. Such deaths often involve multiple drugs of the same type (e.g., benzodiazepines or narcotics), individually present in “therapeutic” amounts, and often in combination with alcohol. Interpretation of blood drug concentrations in these cases has to take into account disease that may be present, and the total amounts of drugs and alcohol. In many cases, these effects may simply be additive, i.e., simply the sum of the individual effects of the drugs involved. In other cases, the effect may be truly synergistic, where the toxicity is greater than would be expected based on the pharmacology and concentrations of the individual drugs. Cases where multiple drugs are present,

with or without alcohol, are probably the most difficult to interpret and rely heavily on the experience of the interpreter and a reliable and complete case history.

12.6.5.4 Adverse Reactions

A death attributed to neuroleptic malignant syndrome (NMS) resulting from therapy with phenothiazine or some other neuroleptics is a good example of a fatal adverse drug reaction.⁵³ Combinations of drugs can result in similar syndromes, such as combination of a tricyclic antidepressant and a monoamine oxidase inhibitor (MAOI) causing serotonin syndrome.⁵⁴ Although not always fatal, a serotonin reaction can result in death and might be considered where there is no other reasonable cause of death and especially where there are elevated concentrations of MAOIs and either tricyclic antidepressants or SSRIs. It should be borne in mind that by the very nature of drug–drug or other adverse reactions, blood concentrations of the drug(s) involved are seldom predictive of the outcome and are often well within the range normally expected from therapeutic doses. In the absence of clinical observations, such fatalities can be very difficult to diagnose accurately.

12.6.5.5 Drug Instability

It should not be overlooked that many drugs are unstable in any biological fluid. Cocaine is probably the most notable example. It is broken down in aqueous solution and enzymatically in blood or plasma to benzoylecgonine and methylecgonine, neither of which has much pharmacological activity. While cocaine may be stabilized to some extent by the addition of fluoride after the blood is collected, the extent of breakdown between death and autopsy must be considered. Unfortunately, there are many variables to consider. First, the toxicity of cocaine itself correlates only poorly with blood concentration, even in the living. There is good evidence that cocaine concentrations in post-mortem blood can increase or decrease, depending on the exact site of collection.^{55,56} There are probably competing effects due to variable breakdown in different areas of the body and true post-mortem redistribution. The collection and measurement of cocaine in vitreous humor has been attempted to overcome these problems. However, it has been shown that cocaine will often, if irreproducibly, increase in concentration with time in the vitreous humor. The mechanism for this has not been proved, but it likely involves post-mortem redistribution from the brain, where cocaine is known to concentrate relative to the blood, into the eye via the optic nerve and other soft tissue. It is possible that time-dependent post-mortem increases in vitreous concentrations may occur for other drugs where those drugs attain higher concentrations in the brain.

12.6.5.6 Interpretation Using Tables of Values

There probably is not a forensic toxicologist or pathologist alive who has not used published tables as a reference when trying to interpret post-mortem blood concentrations. Tables of such values became a necessary evil due to the sheer volume of medical and forensic literature. However, they unfortunately perpetuate the myth that post-mortem toxicology results can be interpreted solely using, or heavily relying on so-called “therapeutic,” “toxic,” and “fatal” ranges. Although tables of drug concentrations can serve as a useful reference point, it should be borne in mind that many of the values in these tables are derived from serum or plasma data from living patients, that the ranges are seldom referenced to published cases, and that they may not take into account or state other variables such as post-mortem redistribution, time of survival after intoxication, or the presence of other drugs, natural disease, or injury. Having stated that, one compilation has attempted to address some of these issues and indeed bases the post-mortem values it lists exclusively on carefully collected femoral blood samples.⁵⁷ In that compilation, values are also provided for “controls,” consisting of deceased subjects, who with certainty died of causes other than intoxica-

tion, and who were not incapacitated at the time for the demise. Such data are equally important as levels in fatal cases and additional compilations using this approach are encouraged.

12.6.6 Conclusion

In the final analysis, post-mortem toxicology results must be interpreted with regard to all of the available information, including medical history, information from the scene, autopsy findings, nature and exact location of the post-mortem samples collected, and the circumstances of the death. Only after weighing all of these variables can post-mortem results be reliably interpreted. Even then, it must be admitted that *reliable* interpretation of some results is simply not possible based on the available information. In many respects, the desirable underlying approach to the interpretation of post-mortem drug concentrations is not much different from that used a century ago: a good scene investigation, medical investigation, laboratory investigation, and the application of common sense. We hope we are also wiser now.

Editor's Note: This chapter covers exciting new methods and materials that were largely experimental or unheard of at the time the first edition of this book was published. Sudden death goes unexplained at least 5% of the time, and perhaps even more often than that. The percentage is

higher in children and young adults. Advances in molecular biology and DNA technology now make it possible to explain many of those deaths.

This development is not without irony. At the same time that many in clinical medicine are expressing frustration about the lack of tangible gains provided by the Human Genome Project 1, and pathologists are wondering about the viability of their field, DNA technology is about to reshape the field of forensic pathology, and most especially the field of drug death investigation. Emerging evidence suggests that the underlying cause of death in many is genetic, and that heart and liver abnormalities may play a role. The problem is that death from a wide variety of genetic defects leaves no histological markers. The ability to identify these “invisible diseases” with postmortem genetic testing has become a reality far more quickly than anyone had ever imagined. It may not yet be “standard of care” to test for cardiac channelopathies, or P450 polymorphisms, but it will be in the not-too-distant future. The introduction of these methods will have an enormous effect on the practice of forensic pathology, and so an introduction has been included in this edition. Some of the more important developments in the postmortem diagnosis of liver and heart disease are discussed in this chapter.

13.1 PHARMACOGENOMICS FOR TOXICOLOGY*

Robert M. White, Sr., Ph.D.¹ and Steven H.Y. Wong, Ph.D.²

¹ Technical Director, DSI Laboratories, Fort Myers, Florida

² Professor of Pathology, Director, Clinical Chemistry/Toxicology, TDM, Pharmacogenomics, and Proteomics, Medical College of Wisconsin, and Scientific Director, Toxicology Department, Milwaukee County Medical Examiner's Office, Milwaukee, Wisconsin

The Great Paracelsus (Phillipus Aureolus Theophrastus Bombastus von Hohenheim-Paracelsus, 1493–1541) is remembered by toxicologists for his famous quote: “All substances are poisons; there is none which is not a poison. The right dose differentiates a poison from a remedy.”² Indeed, the basic principle from the quote still applies today. The right dose of morphine that will produce a blood level of approximately 0.07 to 0.083 mg/L is essential for the relief of pain. An overdose that results in a markedly increased blood level (0.2 to 2.3 mg/L) can cause death due to central nervous system depression.³ In general, the same applies to all chemical substances. However, as an important exception to Paracelsus's statement, there are instances in which a drug should be avoided completely. An example is found in the administration of succinylcholine as a skeletal muscle relaxant in surgery patients. Most patients can convert succinylcholine into inert metabolites through an enzyme called pseudocholinesterase because most patients possess two alleles for the common gene that can produce active enzyme. However, a certain small percentage of patients carries the genes that are aberrant or silent and, thus, either produce protein (enzyme) that is defective in its function or cannot produce the protein that is capable of inactivating administered succinylcholine at all; these patients expire or suffer severe sequelae from administration of the drug.⁴ Along the same line of thinking, the dose of a given drug for certain individuals may differ from that used for the majority of the population due to genetic differences between the individual and the general population (e.g., a reduced dose of 6-mercaptopurine in the presence of reduced thiopurine methyl transferase or TPMT activity due to a genetic deficiency in synthesis of the active enzyme).⁵ Therefore, in the third millennium, an expansion of Paracelsus's statement might be that the “right dose” for one individual may not be the “right dose” or even the right drug for another due to differences in each individual's genetic makeup. The determination of what is the “right

* This chapter was partially rewritten with modifications and updates from Reference 1, with permission from the publisher, Medical Laboratory Observer.

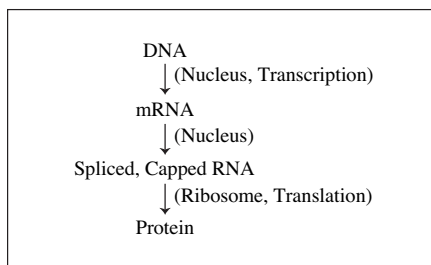

Figure 13.1.1 Central dogma.

dose” and, in some cases, what is even the right drug for a given individual constitutes the reason for the development of the sciences of pharmacogenetics and pharmacogenomics.

Although often used interchangeably, there are subtle differences between pharmacogenetics and pharmacogenomics. Pharmacogenomics is concerned with the systematic assessment of how chemical compounds (e.g., drugs) modify the overall expression pattern in certain tissues. Pharmacogenomics is not focused on the differences between individuals. Rather, pharmacogenomics focuses on differences among several drugs or compounds with regard to a generic set of expressed or non-expressed genes. The focus in pharmacogenomics is on compound variability. In contrast, pharmacogenetics focuses on individual traits with respect to one compound or drug. Thus, pharmacogenetics, which historically actually preceded pharmacogenomics, looks at the responses of different individuals to one drug while pharmacogenomics studies the differences among several compounds with regard to a single genome.^{6–11} For the purposes of this brief introduction, the two terms will be used interchangeably unless stated otherwise.

Before embarking upon a cursory journey through pharmacogenomics, a very brief discussion of DNA (deoxyribonucleic acid) and its products is in order. DNA is the genetic code that determines all of an individual’s characteristics including the synthesis of the proper proteins essential for life. The so-called “central dogma” of molecular biology is outlined in Figure 13.1.1.¹⁰ DNA is a long chain of chemically linked (phosphate bond), single nucleotides. Although there is a great deal more detail to the system due to phenomena such as splice variants,⁸ etc., basically DNA is transcribed in the cell nucleus by an enzyme called RNA polymerase to yield messenger RNA or mRNA. DNA sequences called promoters and enhancers also are required to initiate RNA synthesis. Silencers balance the effects of promoters and enhancers when synthesis is not required. A stop codon (a series of the nucleotides that tells the polymerase to stop transcription) also is required so that only the required RNA and not an almost infinitely long RNA is produced. Regions of the mRNA from DNA that do not code for amino acids are called introns. The introns are spliced out before the completed mRNA is capped (*vide infra*) and exported from the nucleus for translation. The regions of the mRNA that do code for protein are called exons. RNA that has had the introns removed is capped on the 5′ end with a special nucleotide called 7-methylguanosine and has a poly-A (poly-adenosine) “tail” added to the 3′ end. The capped mRNA with its poly-A “tail” is then translated into protein in a cellular apparatus called a ribosome.⁶

Also required before pharmacogenomics can be discussed is a basic knowledge of proteins that are the end product of the transcription of DNA and the translation of RNA. Essentially, a protein is a long chain of chemically linked (amide or peptide bond) amino acids. The sequence in the chain of amino acids is called the primary structure. The chain may form loops and/or helices (secondary structure) and the loops and helices may fold to form the tertiary structure. Further, the protein may exist by itself, associate with other protein chains like itself (e.g., dimerize to form an aggregate of two like chains), or associate with dissimilar protein chains to form the final, active structure, which is known as the quaternary structure. Further, a protein may be chemically and functionally changed (“post-translational modification”) by the addition of phosphate groups (phosphorylation), glucuronic acid groups (glucuronidation), or other groups or by the addition or removal

of amino acids or short stretches of amino acids called polypeptides. The study of proteins, which is closely related, but separate from molecular biology, is called proteomics.¹²

Proteins can act as hormones (e.g., insulin, glucagons, chorionic gonadotrophin, etc.), enzymes, which are biological catalysts (e.g., lactate dehydrogenase, alkaline phosphatase, creatine kinase, etc.), structural components (e.g., troponin, collagens, etc.), receptors (e.g., opiate receptors, cholesterol receptors, etc.), and a plethora of other functions essential for life itself. When a protein is formed from DNA that was in the correct sequence, the DNA is correctly transcribed, and the RNA is correctly translated; a fully functional protein usually results. However, if the DNA code is incorrect (although exceptions exist here, also) or there is a defect in the machinery that creates the protein from the original DNA code, a partially functional protein, a non-functional protein, or even a protein that is deleterious to cell function may be produced. Gene duplication, where the gene is functional and codes for the correct protein, can result in the overproduction of protein.¹³

Also before pharmacogenomics can be discussed, it is helpful to review a few pharmacologic fundamentals. First, although it sounds obvious, before a drug can have any effect on an individual, the drug must somehow enter the individual's body. Entry can be accomplished through inhalation (e.g., a bronchodilator used for the treatment of asthma), absorption through the skin (e.g., a topical anesthetic such as cocaine or lidocaine) or mucous membranes (e.g., pilocarpine eye drops), parenterally (any number of drugs that may be delivered intravenously, intramuscularly, or subcutaneously), or, most commonly, orally (a large number of drugs including such common substances as aspirin and acetaminophen) where the drug is absorbed from the gastrointestinal tract. Once inside an individual, a drug needs to be transported to the site where it will have its effect. A drug may have no action whatsoever (e.g., inulin), may act directly on a receptor to produce the desired effect (e.g., morphine for analgesia), or may require activation (e.g., the production of morphine from codeine for analgesia). Both before and after the desired effect has been produced, drugs may be excreted (multiple routes such as urine and bile) unchanged (e.g., free morphine) or excreted as metabolites (e.g., the excretion of morphine glucuronide, which is an inactive metabolite of morphine) or a combination.¹⁴ Proteins are essential to carry out all of the afore-mentioned steps in drug metabolism.

Proteins play an active role in the disposition of drugs and their metabolites (*vide infra*). Proteins in the intestinal enterocytes such as BCRP (breast cancer resistance protein), MRP2 (multidrug resistance-associated protein), and MDR1 (multidrug resistance protein) are involved in the transport of xenobiotics into the intestinal lumen. A member of the peptide transporter family such as PepT1 facilitates absorption from the gut lumen and tubular reabsorption in the kidney. Drugs such as valaciclovir, valganciclovir, and captopril are known to be transported by PepT1. OCTN2, which is part of the organic cation transporter family, is involved in both the efflux and influx of drugs such as quinidine and verapamil. Although numerous polymorphisms exist among the transporter proteins, their influence on pharmacogenomics is unclear and still in its infancy.¹⁵ However, a clear example of how a protein and a mutation of that protein can affect a drug's absorption is found with the cardiac glycoside digoxin. *P*-Glycoprotein, which is a membrane protein that functions as an exporter of xenobiotics from cells, is a product of the MDR1 (multidrug resistance) gene. Although several models have been proposed for *P*-glycoprotein's action, basically *P*-glycoprotein acts to move xenobiotics from epithelial cells into the adjacent lumen. *P*-Glycoprotein is found in numerous cells associated with excretory function. In the case of digoxin (and certain other drugs), reduced intestinal absorption of the drug can be associated with induction (increased amounts) of the enzyme or the C3435T (cytosine replaces thymidine at position 3435 in the DNA sequence that codes *P*-glycoprotein) mutation of *P*-glycoprotein. Thus, the mutant form of the protein causes a lowered overall intestinal absorption of digoxin by excreting more back into the intestinal lumen than the wild-type protein.¹⁶

Once a drug has entered the bloodstream it is transported to various parts of the body where the drug may be activated or inactivated by certain enzymes (*vide infra*) by a process commonly

Figure 13.1.2 Metabolic pathway for oxidation of ethanol.

referred to as biotransformation or metabolism, be excreted unchanged, interact with a receptor or other location where the desired (and, sometimes, undesired or side effect) action(s) may take place, or be stored (e.g., the retention of 9 -tetrahydrocannabinol or THC in body fat or lead in bone) for future uses such as those previously described. Many drugs and other xenobiotics express their pharmacodynamic action by interacting with a specific protein receptor. As an example, morphine acts at what are called μ receptors. Indeed, polymorphism is exhibited by the various opiate receptors.¹⁷

Perhaps the best-characterized and most extensively studied area in pharmacogenomics is biotransformation, which is commonly referred to as metabolism. Fundamentally, biotransformation or metabolism can be divided into two areas — Phase I and Phase II. Both Phase I and Phase II are designed to make xenobiotics more polar and, thus, more water soluble. By being more polar and more water soluble, metabolites are more easily excreted into excretory fluids such as urine. Phase I reactions include hydrolysis, reduction, and oxidation. Phase I metabolism may activate a drug (known in this case as a prodrug) into a biologically active form, or Phase I may inactivate an active drug. An example of activation is seen with the conversion of Tegafur into the active anticancer agent 5-fluorouracil (5-FU). An example of deactivation is seen with the oxidation of ethanol into acetaldehyde by alcohol dehydrogenase and the further oxidation of acetaldehyde into acetate by aldehyde dehydrogenase. Phase II biotransformation may or may not be preceded by Phase I biotransformation. Phase II biotransformation reactions involve glucuronidation, sulfation, acetylation, methylation, conjugation with glutathione, and conjugation with amino acids such as glycine, taurine, and glutamic acid.¹⁸

Hydrolysis as a Phase I chemical breakdown pathway has been mentioned above in the case of pseudocholinesterase and its variants. Reduction of the drug 5-fluorouracil, which was discussed above under activation of Tegafur, shows polymorphism in the 5-FU reduction when 5-FU is metabolized (deactivated) to its reduction product, 5-fluorodihydrouracil, in rare individuals who are deficient in the enzyme dihydropyrimidine dehydrogenase (DPD). Individuals who are deficient in DPD show toxicity, which may be fatal, to bone marrow and intestines due to increased levels of 5-FU.¹⁵

Since a more polar (and, thus, more water soluble) product usually results, oxidation is one of the commonest metabolic pathways in mammals. Due to genetic polymorphism, the metabolism of the most routinely observed analyte in toxicology, ethanol or ethyl alcohol, actually is more complex than usually visualized by the simple pathway depicted in Figure 13.1.2.

The first enzyme in the oxidation of ethanol, alcohol dehydrogenase, is a zinc-containing dimer, which means that the functional enzyme consists of two protein chains and the element zinc. The subunits are encoded on chromosome 4 by six different genetic loci (ADH1A, ADH1B*1, ADH1C*1, and ADH4 to ADH7; formerly ADH1 through ADH7, respectively). The subunits are designated α , β , γ , π , χ , or σ . ADH1A (formerly ADH1) codes the protein for α subunits. ADH1B (formerly ADH2) codes for β subunits. ADH1C (formerly ADH3) codes for γ subunits. To further add to the complexity of the system, there are three allelic variants of the beta subunit designated β_1 , β_2 , and β_3 and two allelic variants of the gamma chain designated γ_1 and γ_2 arising from, respectively,

ADH1B*1, ADH1B*2, ADH1B*3, ADH1C*1, and ADH1C*2. The nine subunits of ADH can combine to form homodimers (i.e., both chains are identical) and the α , β , and γ chains and their allelic variants heterodimers (i.e., the two chains are different) with each other, but not with the other types of chains. The different molecular forms of ADH are divided into four classes. Class I contains ADH1A, ADH1B*1, and ADH1C*1, which can be considered isozymes. ADH1B enzymes that differ in the type of β subunit are known as allelozymes as are ADH1C enzymes that differ in the type of γ subunit. Accordingly, the protein product of ADH1B*1 is an allelozyme composed of β_1 subunits, the protein product of ADH1B*2 is an allelozyme composed of β_2 subunits, and the protein product of ADH1B*3 is an allelozyme composed of β_3 subunits. Class II contains ADH4, which is made up of two π subunits. Class III contains ADH5, which is made up of two χ subunits. Class IV contains ADH7, which is made up of two σ subunits. It is the Class I and Class II ADH isozymes that are of the most interest to the practicing toxicologist as it is these isozymes that are involved in the oxidation of ethanol and methanol. The protein product of ADH1B*2 is an atypical isozyme that is responsible for an unusually rapid conversion of ethanol into acetaldehyde in 85% of Asians, but is expressed to a lesser degree in Caucasians, Native Americans, and Asian Indians. Conversely, in about 25% of African Americans there is an abundance of the $\beta_3\beta_3$ form. European Caucasians have a predominance of the homodimer from the ADH1B*1 gene.²⁰ Aldehyde dehydrogenase (ALDH) oxidizes aldehydes (like acetaldehyde) to the corresponding carboxylic acid. In all, 12 ALDH genes (ALDH1 through ALDH10, SSDH, and MMSDH) have been identified in humans. ALDH2 is primarily responsible for oxidizing simple aldehydes like acetaldehyde. A genetic polymorphism for ALDH2 has been identified in humans. A high percentage of Japanese, Chinese, Koreans, Taiwanese, and Vietnamese populations are deficient in ALDH2 due to a point mutation (Glu₄₈₇ \rightarrow Lys₄₈₇). This inactive allelic variant of ALDH2 known as ALDH2*2 is found in the same population that has a high incidence of the atypical form of ADH, ADH2*2, which means that these individuals rapidly convert ethanol to acetaldehyde, but only slowly convert acetaldehyde to acetic acid. As a result, many Asians experience a flushing syndrome after consuming alcohol. Thus, what is considered to be very simple by most toxicologists; especially those who deal with driving under the influence (DUI) forensic cases, actually can be quite rich in detail for certain individuals within a diverse array of ethnic groups.^{19–22}

In addition to the example of the oxidation of ethanol given above, numerous other oxidative pathways for xenobiotics exist in humans and other animals. Many of the oxidations of drugs are the result of a group of enzymes known as CYPs (from *CY*tochrome *P*450, the 450 being derived from the cytochrome's maximal absorbance of light at 450 nm). The cytochrome P450s or CYPs are categorized according to amino acid sequence homology. CYPs that have less than 40% homology are placed in the same family (e.g., 1, 2, 3, etc.). CYPs that are 40 to 55% identical are assigned to different subfamilies (e.g., 1A, 1B, 1C, etc.). P450 enzymes that are more than 55% identical are classified as members of the same subfamily (e.g., 2B1, 2B2, 2B3, etc.). The P450 enzymes are expressed in numerous tissues, but are especially prevalent in liver. CYPs so numerous that their complete description is beyond the scope of this basic introduction exist in mammalian physiology.¹⁸ However, the CYPs that are important to human drug metabolism are within its scope.²³

The final step in drug metabolism is elimination. As stated above elimination can occur with the unchanged drug, a drug that has been subjected to Phase I metabolism, a drug that has been subjected to Phase II metabolism, or a combination. Also as briefly discussed above, the proteins involved in elimination can be subject to polymorphism and, thus, are involved in pharmacogenomics.

A few brief examples of the applications of pharmacogenomics are given in the sections below.

13.1.1 Clinical Applications

Three applications of pharmacogenomics are demonstrated in depression, opiate toxicity and forensic toxicology.

13.1.1.1 Depression

To provide therapeutic efficacy, the tricyclic antidepressant nortriptyline must achieve serum levels of 5 to 150 ng/ml.²⁴ Usually, a therapeutic level is achieved by adjustment of a standard dose. Nortriptyline is metabolized to its hydroxy metabolite, 10-hydroxynortriptyline, by CYP2D6. Individuals with different genotypes and multiple copies of CYP2D6 metabolize nortriptyline at markedly different rates. When poor metabolizers of debrisoquin (a drug used to determine an individual's CYP2D6 status) with no functional CYP2D6 gene, extensive metabolizers with one functional CYP2D6 gene, extensive metabolizers with two functional CYP2D6 genes, ultra-rapid metabolizers with duplicated CYP2D6*2 genes, and one ultra-rapid metabolizer with 13 copies of the CYP2D6*2 gene are compared, the results are quite striking. On one end of the spectrum, the individuals with no functional copy of CYP2D6 have maximal levels of serum nortriptyline of 51 to 71 ng/ml. On the other end of the spectrum, an individual with 13 copies of the CYP2D6*2 gene had a maximal serum level of only 13 ng/ml. Needless to say, this represents an outstanding example where a "standard dose" will not necessarily achieve the required serum level of the active drug and, thus, the desired results.¹³

Selective serotonin-reuptake inhibitors such as fluvoxetine, paroxetine, and fluoxetine exert their action probably through the serotonin transporter protein. The serotonin transporter gene (5-HTT) shows several polymorphisms. One polymorphism is in the transcriptional control region upstream of the 5-HTT coding sequence. It is either a 44-base-pair insertion (long variant) or deletion (short sequence). One group has reported that individuals homozygous for the long variant and heterozygous individuals respond better to fluvoxamine than do individuals who are homozygous for the short variant.²⁵ Interestingly, another group reported just the opposite.²⁶ The disparity between the studies is a reminder that other factors that may never be separated out affect genomic expression and phenotypic response.

13.1.1.2 Opiate Toxicity

A 62-year-old male, who had previously received chemotherapy but currently was prescribed only valproate for post-traumatic generalized seizure, is admitted for bilateral pneumonia limited to the lower lobes.²⁷ Although there is no evidence of *Pneumocystis carinii*, yeast is found in the bronchoalveolar lavage. The patient is treated with ceftriaxone, clarithromycin, and voriconazole for yeast and codeine for cough. The patient's level of consciousness deteriorates. Serum BUN and creatinine levels that increase are normalized with hydration. Administration of naloxone results in a dramatic improvement in the patient's level of consciousness.

The patient's blood levels of codeine, morphine, and their metabolites were determined by liquid chromatography/mass spectrometry. The patient's level of codeine was above therapeutic as were the levels of morphine, morphine-3-glucuronide (active metabolite), and morphine-6-glucuronide (inactive metabolite). Duplication or multiduplication of the CYP2D6 gene was determined using restriction-fragment-length polymorphism analysis of the patient's genomic DNA. The CYP2D6 and CYP3A4 phenotypes also were determined.

Dextromethorphan was administered to the patient as a probe after he was stabilized. Because dextromethorphan is metabolized by CYP2D6 into dextrorphan and 3-hydroxymorphinan by CYP3A4, the ratio of dextromethorphan to dextrorphan was less than 0.0005, which was compatible with an ultra-rapid CYP2D6 metabolizer.

Normally, about 80% of codeine is converted into norcodeine by CYP3A4 or converted into codeine glucuronide. The conversion of codeine into morphine by CYP2D6 represents only about 10% of normal clearance of codeine. In the patient described, there was ultra-rapid conversion of codeine into morphine by his three or more CYP2D6 alleles. To exacerbate the situation, the patient's CYP3A4 was inhibited by administration of clarithromycin and voriconazole and the accumulation of glucuronides (acute renal failure).

Thus, in contrast to the clinical scenario in which 7 to 10% of the white population receive no analgesic benefit from codeine due to homozygosity for nonfunctional CYP2D6 alleles, that patient described above had a toxic amount of morphine and one of its active metabolites due to ultra-rapid metabolism. The patient's ultra-rapid metabolism due to multiple copies of the CYP2D6 gene was intensified by inhibition of CYP3A4 that normally metabolizes the majority of the codeine to norcodeine.

13.1.1.3 Forensic Toxicology

This section outlines the application of pharmacogenomics as molecular autopsy, as proposed by Figure 13.1.3.²⁸ Several upcoming chapters by Holmgren and Ahlner,²⁹ Sajantila et al.,³⁰ and Wong et al.³¹ summarize the current practice of using pharmacogenomics as molecular autopsy — an adjunct for forensic pathology/toxicology, by considering long QT syndrome, and effect on driving. Several cases are included to illustrate the applications.

A 9-year-old born with probable fetal alcohol syndrome is treated with a combination of methylphenidate, clonidine, and fluoxetine for multiple behavioral problems. Over a period of time, the individual is hospitalized in status epilepticus followed by cardiac arrest and expires. Based on the levels of fluoxetine and its metabolite, norfluoxetine, in the deceased's post-mortem blood, the adoptive parents are suspected of homicide, and the remainder of the adopted children are removed from the household. Due to the vociferous claims of the adoptive parents that there was no foul play involved, the deceased individual is tested for genetic polymorphism. Indeed, a polymorphism in the CYP2D6, which resulted in the poor metabolism of fluoxetine, was discovered. Based on the results of the post-mortem genetic testing, the adoptive parents of the deceased were exonerated and reunited with the remainder of the children.³²

One of the cases of a recently published study of assessing pharmacogenomic methadone death certification involved a 41-year-old woman who was 6 months pregnant and recently diagnosed with heart murmur and rheumatoid arthritis.³³ She was treated with methadone and tricyclic antidepressants for her depression. After celebrating New Year's Eve with her husband, she was found unresponsive in her living room the following morning. Toxicology analysis showed methadone, 0.7 mg/L, amitriptyline, 1.5 mg/L, and nortriptyline, 2.2 mg/L. Pharmacogenomics tests showed CYP2D6*4 homozygous, corresponding to a poor metabolizer as a result of deficient CYP 2D6 enzyme. The lack of enzyme predisposed her to the inability to hydroxylate methadone, amitriptyline, and nortriptyline, resulting in an overall accumulation and drug toxicity. Death certification showed the cause of death to be mixed drug overdose, and manner of death, accident.

In the study of 25 fentanyl cases, one decedent, a 44-year-old white woman, had a history of drug abuse including cocaine, marijuana, and pain medications and psychiatric problems.³⁴ Complaining to her boyfriend about her knee pain during a rummage sale, she obtained some narcotic patches and put them on. Later in the evening, her boyfriend noticed she seemed disoriented, and after about 24 h, she was found not breathing. One Duragesic fentanyl patch was found on her left upper arm, and another adhered to a blanket. Toxicology analysis showed: fentanyl 19 µg/L and norfentanyl 7.6 µg/L with a metabolic ratio of 2.5, cyclobenzaprine 0.16 mg/L, tramadol 0.06 mg/L, diphenhydramine 0.08 mg/L, and citalopram, 0.22 mg/L. Pharmacogenomics testing showed that she was compound heterozygous for CYP 3A4*1B and CYP 3A5*3, resulting in decreased enzyme activities. Death was certified to be mixed drug overdose for cause of death, and accident for manner of death. Together with findings from the other cases, the higher fentanyl concentration and high metabolic ratios in the individuals with CYP 3A5*3 homozygous variant suggested that CYP 3A5 mediates fentanyl metabolism. Thus, homozygous CYP 3A5*3 variant would result in decreased CYP3A5 enzyme activity.

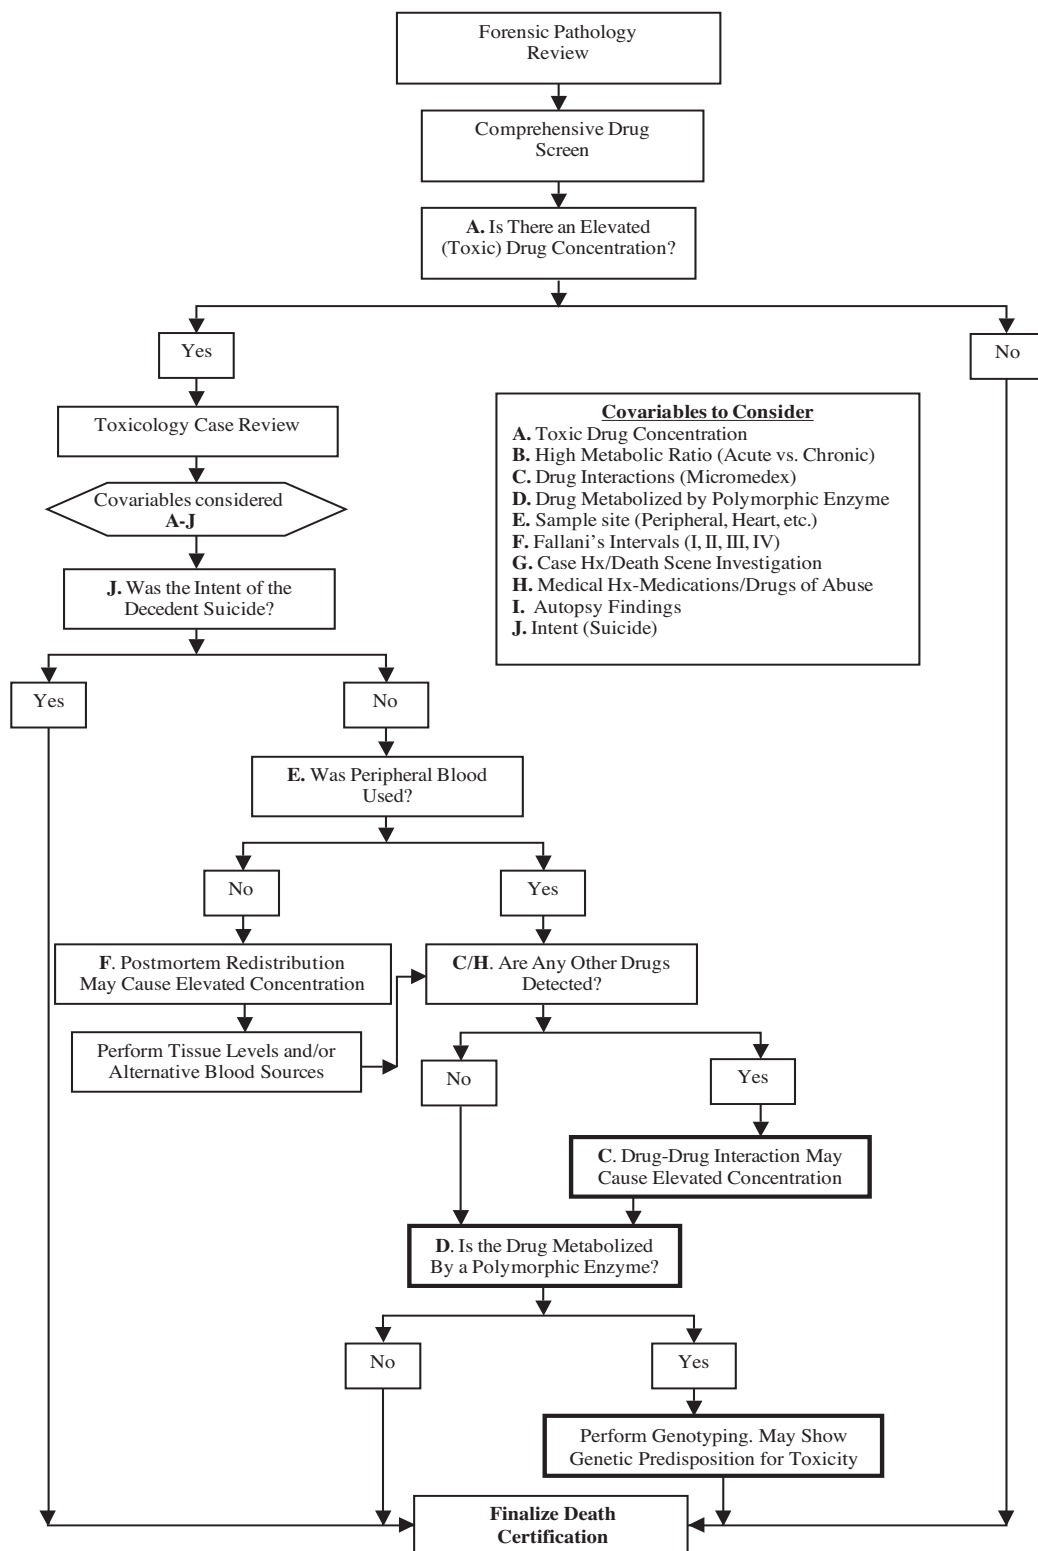

Figure 13.1.3 Application of pharmacogenomics as molecular autopsy.

13.1.2 Conclusions

Pharmacogenomics as molecular autopsy may serve as a useful adjunct for drug death certification for forensic pathology/toxicology. Since most drug deaths involved multiple drugs ingestion, drug–drug interactions will likely contribute to the toxicity and will complicate the interpretation. However, the knowledge derived from post-mortem pharmacogenomics studies would enhance the understanding of pharmacogenomics in “ante-mortem” drug metabolism/therapy, and hence, the emergence of personalized medicine.

GLOSSARY³⁵

Allele: One or several forms of a gene of a single individual compared with other individuals. An allele is present on a specific site (genetic locus) of a chromosome controlling a particular characteristic and giving rise to noticeable hereditary difference. A single allele is inherited separately from maternal and paternal origin. Thus, with the exception of unmatched sex chromosomes, every individual has two alleles for each gene.

Genotype: The precise genetic constitution (i.e., genomes, genes, or alleles at one locus or place) that determines the phenotype (observable characteristics) of an organism.

Heterozygote: An individual who carries a pair of different alleles of a particular gene (inherited from two parents) on each member of a pair of chromosomes.

Homozygote: An individual whose genotype has two identical alleles (each derived one parent) at a given locus or place on a pair of homologous chromosomes.

Phenotype: The observable characteristics or physical appearance of an organism resulting from and determined by its expressed genes.

Polymorphism: “Many faces.” The difference in genetic sequences among individuals, groups, or populations.

Wild-type: The allele, genotype, or phenotype that naturally occurs in the normal population or, in the case of microbes, the standard laboratory strain of a given organism.

Xenobiotic: A foreign chemical including drugs, industrial chemicals, pollutants, pyrolysis products in food, and toxins produced by plants and animals.

13.2 HERITABLE CHANNELOPATHIES AND MYOPATHIES

Kathryn A. Glatter, M.D., Jonica Calkins, M.D., and Sanjay J. Ayirookuzhi, M.D.

Department of Cardiology and Internal Medicine, University of California, Davis, California

Sudden cardiac arrest remains the major cause of death in the U.S. and the developed Western world.^{1–3} Most cases are a consequence of cardiac ischemia, coronary artery disease, and acute myocardial infarction–induced ventricular fibrillation (arrhythmias). Autopsy findings generally reveal atherosclerosis and occluded cardiac vessels in these patients, leading to a clear diagnosis.

However, genetic causes of cardiac arrhythmias are not rare, and the first indication of their presence is often as unexplained sudden death. Some of these disorders may demonstrate gross morphologic alterations at autopsy; hypertrophic cardiomyopathy is the most obvious, but other disorders represent a diagnostic challenge for the forensic pathologists, because at autopsy the heart is structurally normal.

It is important to be familiar with these genetic causes of sudden cardiac death, and the diagnostic difficulties they present, so that they can at least be considered as possible causes of death when the autopsy is otherwise normal. Sudden death in cases of drug overdose may also be due to an ion channel disease and not a simple function of direct drug toxicity. Pathologists need to consider these disorders and other etiologies of cardiac death, as described below.

This chapter contains a brief discussion of the clinical presentation of genetic, molecular, and cellular abnormalities and the appropriate diagnostic measures for the evaluation of channelopathies, cardiomyopathies, and chemical causes of sudden cardiac death (see list below). Finally, we provide an overview for forensic pathologists on the appropriate methods for the collection of tissue samples used for molecular testing of these entities.

Disorders of the Ion Channel

1. Long QT syndromes (LQTS)
2. Brugada syndrome (BS)
3. Catecholaminergic polymorphic ventricular tachycardia (Ryanodine receptor defect) (CPMVT)

Disorders of the Heart Muscle

1. Arrhythmogenic right ventricular dysplasia (ARVD)
2. Hypertrophic cardiomyopathy (HCM)

Chemical Causes of Sudden Cardiac Death

1. Ephedra (“ma huang”)
2. Methamphetamine
3. Cocaine

13.2.1 Disorders of the Ion Channel

13.2.1.1 Long QT Syndromes

LQTS is one of the more common and best known of the ion channelopathies.^{4,5} It can be inherited as a dominant gene or can be seen in cases of acquired LQTS after taking common drugs including antipsychotics, anti-arrhythmic drugs, or allergy medications.^{6,7}

Epidemiology

Currently it is estimated that 1 in 5000 people carry a LQTS genetic mutation.^{4,5} With the inclusion of drug-induced or acquired LQTS cases, many of which have the same genetic ion channel defects as seen with congenital LQTS, some experts believe that the true incidence of LQTS is actually 1 in 1000.^{8,9} Certainly it is one of the more common genetic causes of sudden death, and it is being diagnosed with increasing frequency as more pathologists become aware of its existence.

Clinical Features

Most patients with an LQTS mutation will never experience any symptoms. LQTS families are usually discovered when a young person tragically dies suddenly, has no findings at autopsy, and other family members are found to have a prolonged QT interval on electrocardiogram (ECG). At least 10% of affected patients may present with sudden death as their first (and last) symptom.^{10–13}

Each genetic subtype (described below) has its own trigger for events (Table 13.2.1).^{10–14} LQT1 patients usually experience symptoms (syncope, cardiac arrest, or sudden death) during catecholamine-driven types of activities such as running, exercise, or with strong emotion (e.g., during an argument). An unexplained drowning in a person able to swim could be due to an LQT1 mutation.^{10,13,15,16} LQT2 (*HERG*) mutations may cause sudden death due to auditory triggers, as with an alarm clock or the telephone ringing.^{15–17} Episodes in the rare LQT3 (sodium channel) subtype may occur during sleep or during periods of slow heart rates.^{10,13}

Although LQTS is an autosomal disease, females are far more likely to experience symptoms than males.^{10–14} In some cases LQTS can be diagnosed by noting a prolonged QT_c interval (>450 ms) on the ECG. However, up to 30% of gene-positive patients may have a normal or only borderline prolonged QT_c interval, making diagnosis impossible in some cases.^{10–14,18} Exercise testing may reveal an otherwise concealed form of LQTS.^{19,20}

There is a weak association in the literature between SIDS (sudden infant death syndrome) and LQTS, although probably fewer than 5% of all SIDS cases are due to ion channel mutations.^{21,22} Other, more common causes of SIDS include placing the infant prone, co-sleeping with overlaying by adults, and inborn errors of metabolism.

As with many ion channelopathies causing unexplained sudden death, autopsy findings are unremarkable. Venous blood saved in an EDTA-tube (or perhaps snap-frozen myocardial tissue) can be tested at a research laboratory for the presence of LQTS ion channel mutations.

Table 13.2.1 Long QT Syndrome Genes

Disease	Chromosome Locus	Gene	Gene Product
LQT1	11p15.5	KVLQT1	I _{Ks} subunit
LQT2	7q35-36	HERG	I _{Kr} subunit
LQT3	3p21-23	SCN5A	Na channel
LQT4	4q25-27	ankyrin 2	ankyrin-B
LQT5	21p22.1	<i>minK</i> (<i>KCNE1</i>)	I _{Ks} subunit
LQT6	21p22.1	<i>MiRP1</i> (<i>KCNE2</i>)	I _{Kr} subunit
LQT7	17q23	KCNJ2	I _{Kr} subunit

Pathophysiology

The fundamental defect in LQTS is prolonged ventricular repolarization and a tendency toward the occurrence of torsades de pointes (polymorphic ventricular tachycardia) and ventricular fibrillation.^{4,5} The LQTS ion channel mutation leads to this abnormality in repolarization, and evidence of it can be seen on the ECG as a prolonged QT interval. Beta-blocker medications (described below) do not shorten the QT interval; they are believed to act, in part, by blocking EADs (early after-depolarizations), which initiate the ventricular arrhythmias.

Genetics

To date, a total of seven genes have been identified as causing long QT syndrome.^{23–26} The mutant ion channel that causes clinical LQTS is inherited in an autosomal dominant fashion with incomplete penetrance and was originally known as the “Romano-Ward Syndrome.” With the advent of genetic testing, it has become clear that each LQTS genetic subtype represents a unique disease, with different triggers to arrhythmias. The genes that encode the potassium channels *KVLQT1* (on chromosome 11) and *minK* (on chromosome 21) interact to form the cardiac I_{Ks} (inward slow potassium) current; mutations in each cause LQT1 and LQT5, respectively.^{5,23,24} The potassium channels *HERG* (on chromosome 7) and *MiRP1* (on chromosome 21) interact to form the I_{Kr} (inward rapid potassium) current, and defects in each cause LQT2 and LQT6, respectively.²⁵ Mutations in the sodium cardiac channel *SCN5A* cause LQT3 (on chromosome 3).²⁶ The gene responsible for LQT4 was recently identified as a mutation in the ankyrin-B protein.²⁷ The potassium channel mutations cause a “loss of function” in the channel (or a “dominant-negative effect,” in the case of the *HERG* mutation), whereas defects in the sodium channel cause a “gain of function.”^{4,5} LQT7 is due to a defect in the α -subunit of the I_{Kr} channel (gene product *KCNJ2*).

In the unlikely event that a mutant copy of the I_{Ks} channel is inherited from each parent (mutations in the *KVLQT1* and *minK* genes), the child will suffer from a clinically severe form of autosomal dominant LQTS, and from autosomal recessive congenital deafness. This condition is known as the “Jervell and Lange-Nielsen syndrome” (JLNS).^{28,29} JLNS was first described in 1957 in a Norwegian family in which three congenitally deaf children died suddenly before the age of 10.³⁰ It is actually quite rare, with an estimated incidence of 1.6 to 6 cases per million.²⁹

In a somewhat more likely event, it is possible that an individual carrying a *KCNH2* mutation on a mutant allele might also carry a different *KCNH2* polymorphism on the nonmutant allele. Relatives who inherit the one without the other would be asymptomatic, but when both mutations are simultaneously present, reduction of I_K would be substantial and result in a clinically significant form of LQTS. This situation has actually been demonstrated to occur in humans, raising the possibility that compound mutations may be more common than had previously been suspected.³¹

Treatment

There is no consensus on how to treat patients with LQTS.^{4,13,32} Most physicians would advocate an implantable defibrillator (ICD) for those patients who have survived a cardiac arrest, or possibly even in those with syncopal events.³³ Dual chamber pacemakers, even with beta-blocker therapy, have been shown to be ineffective in symptomatic patients.³⁴

It is generally recommended that beta-blocker therapy should be initiated in asymptomatic LQTS patients.^{11–14} The exact dose or type of beta-blocker medication to be used is unclear. In patients unable (or unwilling) to take medications, an ICD may then be recommended. Restriction from heavy physical activity is also suggested in affected patients. Data from the International LQTS Registry have shown that symptomatic LQT1 patients have a low recurrence rate after starting beta-blocker medication (19% recurrence), LQT2 patients have an intermediate rate (41% recur-

rence), and LQT3 patients a higher rate (50%).¹⁰ Sympathectomy to modify the effect of adrenaline upon the heart has been shown to be ineffective at preventing events.³⁴

13.2.1.2 *Brugada Syndrome*

The Brugada syndrome (BS) is another inherited ion channelopathy that causes unexplained sudden death, particularly in middle-aged males.^{35–37} It is relatively common in southeast Asia and should particularly be considered in the autopsy of subjects with this ethnicity.³⁸

Epidemiology

A Brugada syndrome consensus report published in 2002 estimated the incidence of the disease worldwide at up to 66 cases per 10,000 people.³⁹ Although it is an autosomal dominant disease, it affects males more commonly than females, in an 8:1 male:female ratio. The reason for this gender difference is unknown. The gene is much more prevalent in Southeast Asia than in the U.S., and Brugada syndrome is thought to cause the entity known as *Lai Tai* (“death during sleep”) in Thailand, a relatively common cause of sudden unexplained death among young healthy men.³⁸

Clinical Features

The Brugada brothers reported eight cases of cardiac arrest in 1992, in young healthy patients with right bundle branch block patterns on ECG.⁴⁰ Since then, more has been learned about BS, although much about the disease remains a mystery.^{41,42} It is not known why some patients with Brugada become symptomatic and others remain clinically silent. However, once BS subjects experience a symptom (syncope or aborted cardiac arrest), it becomes a very lethal disease with a high clinical penetrance.^{43–45} Several studies have found that the 5-year recurrence rate following a resuscitated cardiac arrest was 62%.^{39,41,43–45} Most arrhythmic events occur for the first time when patients are in their early 40s, but episodes have been described over a wide age range (2 to 77 years). Symptomatic patients with Brugada experience polymorphic ventricular tachycardia degenerating into ventricular fibrillation, leading to syncope or even death. The episodes occur most commonly during sleep but may also happen with exercise or at rest.

The ECG in a patient with Brugada is frequently abnormal and provides the best way to diagnose BS. A right bundle branch block-type pattern is often noted in right precordial leads V1–V3 with concomitant ST segment elevation.^{35–37,46} In many patients with BS, the ECG abnormalities can normalize or be unmasked by pharmacologic challenge with a sodium channel blocking drug such as procainamide, flecainide, or ajmaline.^{47,48}

Many patients with Brugada will have abnormal test results during invasive electrophysiology (EP) studies.^{49,50} Inducibility of malignant ventricular arrhythmias in this group of patients is not rare, and it may portend a worse clinical prognosis than for those patients who have normal EP studies.^{35–37,49,50} The usual cardiac tests in BS are normal including echocardiogram, cardiac magnetic resonance imaging (MRI), and biopsy. Autopsy findings of the heart in patients with BS are also unremarkable.

Pathophysiology

The mutation in the *SCN5A* gene results in either a reduced sodium channel current or failure of the sodium channel to express. The disease is caused by a defect in the α -subunit of the cardiac sodium channel gene (*SCN5A*).^{37,41,51,52} Numerous *SCN5A* mutations have been described that produce BS, but most lead to a “loss of function” in the cardiac sodium channel. Interestingly, LQT3 (a completely different disease) is also due to mutations in the *SCN5A* gene but leads to a “gain of function” in the sodium channel.^{51–55}

The mutant sodium channel demonstrates more abnormal function at higher temperatures. There are numerous reports in the literature of patients with BS experiencing symptoms during febrile illnesses.^{35–37}

Recently it has been shown that the Y1102 polymorphism of the *SCN5A* gene is present in 13% of African Americans, and that its presence has been linked to the occurrence of lethal arrhythmias in African American families with ventricular tachycardia. The prevalence of the Y1102 polymorphism in a series of sudden deaths in this population has been established; it is present in 28% of African Americans who die of unexplained arrhythmias. Adjusted for age and sex, the relative risk of an unexplained arrhythmic death in individuals with this polymorphism was 8.4 (95% CI 2.1 to 28.6, $P = 0.001$) when compared with noncardiac deaths in this subgroup. The presence of the Y1102 allele appears to be a risk factor in African Americans for sudden cardiac death even in the absence of obvious morphological findings.⁵⁶

Genetics

BS is an ion channelopathy inherited in an autosomal dominant fashion. To date, only 20% of Brugada cases have been linked to the *SCN5A* gene; the precise ion channel mutations causing the remaining 80% of cases are unknown.^{40–42} The *SCN5A* gene is one of the largest ion channel genes known, with at least 28 exons identified thus far.^{51,52}

Treatment

Medications are largely ineffective at treating BS.³⁹ Amiodarone, beta-blocker, and calcium channel blocking agents have all been tried and do not prevent sudden death in high-risk patients, although sotalol may be useful.⁵⁷ The recommended treatment for symptomatic patients with BS is ICD implantation, particularly as the recurrence rate for such subjects is high. Patients who have not yet experienced an arrhythmic event but spontaneously exhibit the abnormal ECG findings are at intermediate risk for an episode and may benefit from prophylactic implantation of a defibrillator.^{49,50,58}

13.2.1.3 Catecholaminergic Polymorphic Ventricular Tachycardia

CPMVT is a newly described inherited disorder of cardiac calcium channels. It is another arrhythmogenic disorder characterized by sudden unexplained death associated with exercise.

Epidemiology

The disease has thus far been described in several Finnish and Italian families.^{59–62} The epidemiology of this disorder has not yet been fully characterized and is so far limited to small case series. Its true incidence is likely much higher than is currently appreciated since most cases are undiagnosed.

Clinical Features

CPMVT was first described by Leenhardt et al. in 1995 in 21 children.⁶³ This disorder is characterized by syncopal spells in childhood and adolescence, which are often triggered by exercise or stress (catecholamines). Cardiac arrest and sudden death also occur. The disease has a mortality of 30 to 50% by the age of 30 in affected individuals.⁶² Due to its autosomal dominant nature, there is often a family history of unexplained sudden death.

The resting ECG of a patient with this disorder is usually unremarkable, as are cardiac imaging studies (echocardiogram, angiogram, cardiac MRI, etc.).^{62–65} Patients with CPMVT may experience bi-directional or polymorphic ventricular tachycardia with exercise stress testing, with emotional stress, or during infusion of adrenaline (isoproterenol).^{64,65} Up to 30% of such patients have been

initially misdiagnosed as having LQTS in one study.⁶¹ Autopsy findings in subjects with CPMVT are generally normal.

Pathophysiology

Defective calcium channels formed as a result of the mutations in the ryanodine receptor gene *RyR2* lead to abnormal conduction, which predispose the heart to ventricular tachycardia and sudden death.^{59–62,66} *RyR2*, the gene encoding the cardiac calcium channel, is responsible for mediating the coupling of the cell's electrical excitation and mechanical contraction. Cellular depolarization leads to release of Ca^{2+} from the sarcoplasmic reticulum via *RyR2* and mechanical contraction. Sudden death is hypothesized to occur as the result of torsades de pointes or ventricular fibrillation due to the abnormal calcium channel handling.

Genetics

CPMVT is due to a defect in the cardiac ryanodine receptor (*RyR2*) gene, which is inherited in an autosomal dominant fashion.^{59–62,66} Ryanodine receptors are intracellular calcium channels that regulate the release of calcium from different cell sites. Three different isoforms of the ryanodine receptor are known, and a different gene encodes each. They are the largest ion channels yet described. *RyR2* (encoded by 105 exons) is characteristically found in the heart while *RyR1* is found in skeletal muscle.

Because this entity is newly described and the genes encoding the mutant calcium channel are so large, no commercial genetic screening is currently available for CPMVT.

Treatment

Beta-blockers form the mainstay of therapy in this condition. In patients who have survived cardiac arrest or are felt to be at particularly high risk for sudden death, an ICD is offered.^{61,65}

13.2.2 Disorders of the Heart Muscle

13.2.2.1 Arrhythmogenic Right Ventricular Dysplasia

ARVD is a newly recognized disorder that is a cause of unexplained sudden death in otherwise healthy young adults, particularly young athletic men.^{67–69} Particularly in the early stages, affected patients may have grossly normal heart function.

Epidemiology

The true incidence of ARVD is unknown. In a prospective, detailed autopsy-based study in the Veneto region of northern Italy, 20% of unexplained sudden deaths in subjects under age 35 were found to have ARVD, including 22% of young athletic men who died suddenly in the region.⁷⁰ It is unclear if northern Italy simply has an abnormally high incidence of the disease, or if this reflects the true incidence of the disease. However, it is likely a much more common entity than initially appreciated as most cases go undetected.

Clinical Features

Unfortunately, the initial presentation of ARVD clinically is often the unexplained sudden death in a healthy, athletic male. Patients experience ventricular arrhythmias from the diseased right ventricle. These range from benign premature ventricular complexes (PVCs) to ventricular tachy-

Table 13.2.2 ARVD Diagnostic Criteria

ECG Findings

Arrhythmias
Right ventricular tachycardia or premature beats
Family history
Confirmed at autopsy
Structural findings
RV global hypokinesis with preserved LV function

cardia or even ventricular fibrillation and cardiac arrest.^{71–74} ARVD was first described briefly in 1961, and in greater detail in 1977.^{75,76} The Study Group on ARVD/C has defined specific criteria to aid in the diagnosis of ARVD (Table 13.2.2).⁷⁷

ECG findings include a complete or incomplete right bundle branch block during normal sinus rhythm with T wave inversion in leads V₁ to V₃. An epsilon wave, a terminal notch in the QRS, may also be present.^{67–69,71–73} A signal-averaged ECG (SAECG) is also characteristically abnormal.⁷⁷

Echocardiographic findings may be normal or reveal a variety of abnormalities in the right ventricle including RV wall thinning, dilatation, or dysfunction.^{67–69,71–73,78} Cardiac MRI can sometimes be useful as it may reveal the fibrofatty infiltration of the RV free wall.^{79,80} Biopsy of the RV septum (done in the septum and not in the free wall, due to free wall thinning) is often not helpful because involvement of the septum in ARVD is sporadic.

ARVD represents one of the few genetically based causes of sudden death that can be identified at autopsy, at least in grossly abnormal cases. The pathologist may find diffuse or segmental loss of myocardium in the right ventricular free wall, with concomitant replacement with fibrofatty tissue.^{67–69} Two thirds of such patients have patchy, acute myocarditis-type of findings with lymphocytic infiltration and cell death.^{71–73} Up to 50% of patients with ARVD have right ventricular aneurysms at autopsy.^{71–73,77}

Patients can have progressive dilatation and failure of the right ventricle over time, which can also occasionally involve the left ventricle, leading to a diffuse cardiomyopathy. One study found that 76% of ARVD subjects had histologic involvement of the left ventricle.⁷⁷

Pathophysiology

The pathophysiology of ARVD is unclear. It likely represents a complex interplay among genetic predisposition, cellular mechanisms, and unknown environmental factors.^{67–69,77} Several consistent features of ARVD can be noted: apoptosis (programmed cell death), a component of inflammatory heart disease (e.g., acute myocarditis), and myocardial dystrophy. The disease is progressive over decades in some patients, whereas it is relatively quiescent, for unknown reasons, in others.

Genetics

At least seven distinct chromosomal loci for ARVD have so far been located.^{81–85} These loci include two on chromosome 10, two on chromosome 14, and one each on chromosomes 1, 2, and 3. One autosomal recessive form of ARVD is associated with palmoplantar keratoderma and woolly hair.⁸⁶ It is due to a mutation in the gene for plakoglobin. Another syndrome found in Ecuador involves a recessive mutation in the gene for desmoplakin.⁸⁷ Both are components of desmosomes, which form the major cell adhesion junctions. Currently, there is no commercial genetic testing available to diagnose ARVD.

For most cases of ARVD, the genetic linkage is unclear. Up to 30 to 50% of the cases will have an associated family history consistent with ARVD (including sudden death).^{71–73,77}

Treatment

There is no consensus for how to treat ARVD.⁷⁷ In those patients who have survived cardiac arrest, implantation of an ICD is generally recommended to avoid sudden death.⁸⁸ Pharmacologic therapy with beta-blocker or antiarrhythmic medications has also been suggested.⁷⁷ Radiofrequency ablation during electrophysiology study of ventricular arrhythmias has also been attempted.⁸⁹

13.2.2.2 Hypertrophic Cardiomyopathy

HCM is one of the oldest known non-atherosclerotic causes of sudden death. It was first described in 1958.⁹⁰ It has been called HOCM (hypertrophic obstructive cardiomyopathy) and also IHSS (idiopathic hypertrophic subaortic stenosis) despite that 75% of affected patients do not have a sizable resting outflow gradient.^{91,92} It is a polygenic, relatively common, genetic cause of sudden death, particularly in young athletes.

Epidemiology

HCM is actually the most common genetically associated form of sudden cardiac death. It is estimated that 1 in 500 people (0.2% of the general population) carry an HCM genetic mutation.^{93,94} However, the phenotypic presentation or clinical penetrance of the disease is much lower. Most patients with an HCM mutation will not demonstrate clinical manifestations of the disease during life.

Clinical Features

The hallmark feature of HCM, when present, is myocyte disarray.^{92,95,96} The clinical diagnosis of HCM during life is made most reliably by echocardiography. Severe ventricular wall thickening can be noted. A normal left ventricular wall thickness is generally <12 mm, but thicknesses >30 mm are not unusual in severe cases of HCM.^{97–101} Marked septal hypertrophy is often an age-dependent effect and may not be seen initially in young patients. In most cases, the left ventricle is affected diffusely, or it may demonstrate ASH (asymmetric septal hypertrophy).^{95–101} In contrast, in the Japanese variant of HCM, the apical left ventricle is primarily affected and shows abnormal thickening.^{92,95–101}

At autopsy using detailed pathologic examination, one can frequently see hypertrophied myocytes with bizarre shapes, chaotic cellular alignment, and gross cellular disarray in the left ventricle.^{102–106} The disarray is most evident in the mid-portion of the septum. Patchy areas of myocardial scarring and fibrosis can be seen, a lesion that is thought to be due to the presence of abnormal intramural coronary arteries.^{107,108}

Pathophysiology

Syncope in these subjects may occur due to arrhythmias, or it may be the result of outlet obstruction due to ventricular hypertrophy and cavitory obliteration.^{90,97,98} Dehydration can trigger syncopal events in such patients. Sudden death in HCM is primarily due to electrical abnormalities generating ventricular arrhythmias.^{92,97,109–112} In support of this view, one large study of patients with HCM, in whom defibrillators were implanted, demonstrated that nearly 25% of the patients had documented ventricular arrhythmias over a 3-year follow-up period.¹¹³

The disease may be progressive in certain individuals. Cardiomyocytes continue to hypertrophy over years, but in a clinically silent manner that may lead ultimately to an end-stage, dilated cardiomyopathic picture.^{92,97,98} Depending on the timeframe during which the patient is evaluated, the HCM-affected heart could appear grossly normal, markedly hypertrophied, or dilated, which makes the diagnosis difficult.

Genetics

The polygenic and multicellular nature of HCM makes it a frustratingly difficult disease to diagnose unless gross histopathologic abnormalities are found on ECG or at autopsy. At least ten different genes encoding the cardiac sarcomere have been implicated in HCM.^{92,97,98,114} More than 150 unique mutations have been reported since the first genetic cause for HCM was identified in 1990.¹¹⁵ Most such mutations are missense mutations found in the proteins of the cardiac sarcomere and are located in the β -myosin heavy chain, cardiac troponin T, or myosin binding protein-C.^{111–119} Although the disease is autosomal dominant, a family history of syncope or sudden death may be lacking, and the disease has variable clinical penetrance.

Within the β -myosin heavy chain gene (*MYH7*), numerous mutations have been described as malignant mutations associated with a poor clinical prognosis.^{118–121} These particular mutations seemed to be associated with a severe clinical phenotype including progression to end-stage heart failure or sudden death, a relatively high penetrance of the disease, and extreme left ventricular wall thickness.^{92,97,98,112,117,118}

Treatment

There are no formal guidelines for treating asymptomatic patients with HCM.^{92,97,98} In symptomatic patients with shortness of breath, treatment with medications that reduce the outflow gradient remains the mainstay of therapy.^{92,97,98,122,123} Such medications include beta-blockers or calcium channel blockers. In very symptomatic patients with a large (>50 mm) gradient, the outflow gradient can be reduced by surgical myomectomy or by catheter-based alcohol ablation.^{92,97,98,124,125} The latter is a relatively new technique, which causes a controlled myocardial infarction and thus reduces the obstruction to outflow.

In those patients deemed at high risk for an arrhythmic event, an ICD may be implanted to avert sudden death.

13.2.3 Drug Causes of Sudden Death

Clearly, many medications and drugs of abuse can lead to cardiac arrhythmias and sudden death. A detailed description of these topics is beyond the scope of this chapter. However, we consider three major causes of sudden death that should be considered by the pathologist at autopsy: ephedra (or ma huang), methamphetamine, and cocaine.

13.2.3.1 Ephedra

Ma huang is a popular herb derived from the genus *Ephedra* used for over 5000 years in Chinese folk remedies.¹²⁶ It is a natural source of ephedrine taken in various vitamin or other supplements to promote weight loss and boost energy. Ephedrine and its derivatives function in the body by increasing the availability of naturally released catecholamines.¹²⁷ Its physiologic effects on the body include increasing the heart rate, raising the cardiac output, and elevating the vascular resistance.¹²⁸ It is excreted in the urine and has a serum half-life of 2.7 to 3.6 h.¹²⁹

Before the supplements were withdrawn from the market, it was one of the most widely used herbal supplements in the world. Even though ephedra-containing supplements are no longer for sale, millions of consumers still use ephedrine on a daily basis in the form of over-the-counter asthma preparations. It is puzzling that these asthma preparations, which have been available for more than 50 years, were never associated with any of the complications attributed to the supplements. An estimated 12 million consumers in the U.S. alone purchased over-the-counter ephedra-containing preparations in 1999.^{130–132} Caffeine is also a common ingredient in ephedra preparations;

the combination of the two drugs, when taken in excess, clearly can cause ventricular arrhythmias, hypertension, or cardiovascular collapse.

Numerous case reports have linked ma huang to cases of cardiovascular disorders, sudden death, and hemorrhagic stroke.¹³³ One analysis of adverse event reports evaluated 926 possible cases of ephedra toxicity reported to the FDA from 1995 through 1997.¹³⁰ The authors identified 37 major cardiovascular events they thought likely to be ma huang related, including 16 strokes, 11 cardiac arrests, and 10 myocardial infarctions. The average age of the 37 patients was only 43 ± 13 years and included 23 women.

Pathologists should consider testing for ephedra/ma huang particularly in young, otherwise healthy subjects who die suddenly with a normal autopsy, or if autopsy reveals early-onset vascular disease such as strokes or myocardial infarction.^{134–137} Particular attention should be paid to a history of vitamin supplement ingestion in such patients.

13.2.3.2 Methamphetamine

Methamphetamine is a central nervous stimulant that was first synthesized by a German chemist in 1887.¹³⁸ It is an odorless, crystalline powder that is soluble in alcohol or water. Its precursors are ephedrine and pseudoephedrine.

Its sympathomimetic actions produce hypertension, elevated heart rate, ischemia, vasoconstriction, and other adrenergic-type of stimuli upon the heart. Acute aortic dissection has been described at autopsy in methamphetamine users.¹³⁹ Myocardial infarction, chest pain syndromes, and coronary artery disease have been found in such patients, and a direct toxic effect on myocytes has been implicated for methamphetamine.^{140–142} Methamphetamine may promote ventricular arrhythmias and sudden death with its use.¹⁴³ Chronic use may lead to a dilated cardiomyopathy.^{144–147}

Methamphetamine use is increasingly popular and should be considered in the autopsy evaluation when present, but usually there are other stigmata present suggesting the diagnosis, and sudden cardiac death with a negative autopsy is rare in a methamphetamine abuser.

13.2.3.3 Cocaine

Cocaine (benzoylecgonine) is an alkaloid originally extracted from the leaves of the *Erythroxylon coca* plant.¹⁴⁷ It is estimated that at least 30 million people in the U.S. have used cocaine at some point. Cocaine acts at both the central and peripheral adrenergic nervous system by blocking the reuptake of norepinephrine and dopamine from presynaptic terminals. These effects lead to a net stimulatory effect upon the cardiovascular system.^{148,149}

Cocaine causes a variety of cardiac complications. Its basic pathophysiologic effect is to induce an adrenergic overload leading to acceleration of the heart rate, proarrhythmic effects, and even cardiac collapse.^{147,148,150,151} Cocaine increases myocardial oxygen demand acutely while concomitantly reducing myocardial oxygen supply with its direct vasoconstrictive effects on the coronary arteries. It promotes intracoronary thrombosis and platelet aggregation in the absence of coronary atherosclerosis, leading to vascular injury.^{147,148,150–152} Finally, long-term cocaine use has been associated with premature and accelerated atherosclerosis.¹⁵⁵

The pathologist should consider cocaine toxicity as an adjunctive diagnosis in the unexplained sudden death of seemingly healthy subjects. However, as is true for methamphetamine abusers, sudden death with a negative autopsy is an uncommon finding in a cocaine abuser.

In addition to its direct cardiac effects (e.g., myocardial infarction, stroke, aortic dissection, cardiac arrhythmias), cocaine has been found to directly block the *HERG* potassium channel.¹⁵⁷ This finding represents yet another way cocaine may cause sudden cardiac death, and is particularly important, since *HERG* blockade would not be associated with any identifiable anatomic markers.

13.2.4 Molecular Diagnosis of Cardiovascular Disease

With the explosion of molecular techniques, DNA testing on peripheral blood and tissue has revolutionized the diagnosis of genetic causes of sudden death. We describe the basic methods of tissue preparation and DNA analysis as a useful overview for the clinical pathologist and coroner.

13.2.4.1 Collection of DNA from Blood Samples

It is easiest to amplify DNA that will be used for genetic testing when it is taken from blood samples.^{158,159} Ideally, the medical examiner or pathologist would collect the samples at the time of autopsy. At least 15 ml of blood should be collected in EDTA-containing tubes, in order to prevent coagulation and degradation of the DNA. The tubes are then stored at 4°C until the DNA can be extracted for analysis, which should be within 1 week, although sometimes DNA can be extracted up to 4 months after collection. If the blood samples are collected in tubes that do not contain an anticoagulant, the DNA should be extracted promptly (within days of the initial collection).

13.2.4.2 Collection of DNA from Tissue Samples

Extraction of high-quality DNA from tissue that can be used for PCR (polymerase chain reaction) amplification is much more problematic than using blood samples. It is often difficult to amplify long fragments of DNA from formalin-fixed and paraffin-embedded tissue because formalin fixation may damage the DNA, as may long storage in the tissue blocks prior to analysis. Formic acid may also form in the sample making PCR difficult, if not impossible^{160,161} Formic acid hydrolyzes the DNA and creates single-strand nicks in the DNA. In post-mortem tissues fixed in nonbuffered formalin (usually in tissue preserved more than 20 years ago), DNA fragments longer than 90 base pairs cannot be amplified.

There are a variety of published methods to extract DNA from preserved tissue.^{162,163} Many involve a phenol-chloroform digestion and washing step. Commercial kits are also available that may simplify the methodology. One recent paper described a “pre-PCR restoration process” in which the single-stranded DNA nicks are repaired with Taq polymerase prior to PCR amplification, greatly enhancing the length of DNA pieces that could be amplified.¹⁶⁴

An alternative method for obtaining usable DNA from tissue collected at autopsy is to snap-freeze fresh myocardial tissue in liquid nitrogen, and store it at –80°C until DNA extraction is performed. Using this method allows the extraction process to be deferred for many months. Clearly, collection and preservation of tissue or blood samples for future DNA analysis is cumbersome, time-intensive, and costly. However, it may be of great assistance in determining the cause of death if tissue is carefully preserved for future DNA testing, especially in those cases where a genetic cause of sudden death is suspected.

Acknowledgments

This work was funded in part by an American Heart Association Beginning-Grant-in-Aid, Western States Affiliates, to Dr. Glatter.

14.1 DUI DEFENSES

Alan Wayne Jones, D.Sc.¹ and Barry K. Logan, Ph.D.²

¹ Department of Forensic Toxicology, University Hospital, Linköping, Sweden

² Director, Washington State Toxicology Laboratory, Department of Laboratory Medicine, University of Washington, Seattle, Washington

After prohibition was abolished in the United States in 1933, consumption of alcohol escalated as did many of the negative consequences associated with too much drinking. Among other things, the number of alcohol-related accidents within the home, at work, and on the roads increased alarmingly.^{1,2} Alcohol and transportation made a poor mix, and in efforts to curb this new wave of road-traffic accidents and deaths on the highways, more effective legislative measures were urgently needed.^{3,4}

The first laws prohibiting driving under the influence of alcohol (DUI) appeared in the 1920s, but the criteria used to demonstrate impairment and unfitness to drive were not very sophisticated. These included the smell of alcohol on the breath, the ability of a person to walk a chalk line, and various behavioral signs and symptoms of inebriation.⁵ Gaining a conviction for drunk driving was by no means certain, unless the suspect showed obvious signs and symptoms of gross intoxication.⁶ It was strikingly obvious that more sensitive and more objective methods were needed to decide whether a person was under the influence of alcohol. Following the lead of some European countries, efforts in the U.S. were directed toward measuring the concentration of alcohol in blood and other body fluids as evidence of intoxication.⁷ However, quantitative studies of the relationship between blood-alcohol and impairment were virtually nonexistent at this time.

These efforts led to the first statutory limits of blood alcohol concentration (BAC) for driving being set at 150 mg/dL (0.15 g/dL), a conservatively high level.^{8,9} Subsequently, this threshold BAC for driving has progressively been lowered, first to 100 mg/dL (0.10 g/dL) and in all U.S. states the limit is now set at 80 mg/dL (0.08 g/dL).¹⁰ For young (< 21 y) drivers an even lower BAC, so-called zero tolerance limits, has been sanctioned (0.00 to 0.02 g/dL).¹¹ Legal limits of blood alcohol concentration differ from country to country and also within regions of the same country, e.g. the various states in Australia.¹² Lowering the legal alcohol limits for driving even further is supported by many national and international medical societies including the American Medical Association.¹³ Judging by recent trends in Europe, it seems that most countries are aiming for a threshold BAC limit of 50 mg/dL (0.05 g/dL); France approved a 0.05 g/dL limit in 1995, whereas Sweden adopted 0.02 g/dL in 1990.¹²

Punishment and sanctions for those found guilty of drunk driving have become increasingly severe and include suspension of the driver's license, heavy fines, and sometimes a mandatory term of imprisonment.¹⁴⁻¹⁶ The first DUI statutes stipulated that the concentration of alcohol present in body fluids (blood, breath, or urine) was admissible as presumptive evidence of unfitness to drive, but that this was a rebuttable presumption.^{4,6} In contrast, most of the DUI statutes in operation

today are the so-called per se laws, under which the person's BAC or breath alcohol concentration (BrAC) is the sole deciding factor necessary as proof of unfitness to drive.^{15,16} In short, a person can be found guilty of drunk driving without exhibiting visible signs of intoxication when alcohol concentration per se statutes are in operation.¹⁶ This legal framework, whereby the concentration of alcohol in a specimen of blood or breath determines guilt or innocence, places high demands on the analytical methods used for forensic purposes. Moreover, pre-analytical factors such as sampling, transportation, storage and handling of specimens needs to be carefully regulated and controlled. The combined influences of per se legislation, the compelling objective standard of proof provided to juries in the numerical value of the BAC or BrAC result, and the increasingly harsh penalties imposed on those found guilty of DUI explain, at least in part, the vigorous defense attacks against prosecution evidence based on results of BAC or BrAC determinations.

Soon after chemical tests for intoxication were introduced and used on a large scale, the reliability of the approved methods and the results obtained were increasingly being questioned.⁴ The practice of running duplicate determinations on the same specimen or obtaining two or more specimens of the same or different body fluids (e.g., blood and urine) and testing these by different analytical methods has much to recommend it.^{14,15} Defending drinking drivers has become a popular business and many lawyers specialize in this area of jurisprudence. A plethora of textbooks and newsletters are available that provide detailed information about the science and law of DUI litigation.¹⁷⁻²¹ These typically present recent examples of DUI case law, reviews and opinion of articles published in scientific peer-review journals, and hints and tips for developing more effective strategies for defending and also for prosecuting drunk drivers.²²

This review article discusses the strengths and weaknesses of common DUI defense challenges. The work is subdivided into four main sections. The first deals with general attacks on potentially incriminating evidence, the second focuses on challenging results of urine alcohol analysis, the third deals with scrutiny of blood sampling and analysis, and the fourth section is concerned with the use of evidential breath-alcohol instruments. Procedural aspects of the DUI offense, such as whether the arresting police officer followed the correct protocol when the driver was apprehended, had reasonable suspicion or probable cause for making the arrest, conducted the field sobriety tests properly, or gave the appropriate warnings demanded by the local rules and regulations prior to administering the chemical test, are not considered. The chemistry and physiology of forensic alcohol testing are the main focus of this review and much of the perpetual nit-picking about procedural issues often raised in DUI litigation are omitted.

An extensive list of references is provided, and most citations refer to articles published in peer-review U.S. and European English language journals. However, a bimonthly journal from Germany called *Blutalkohol* (blood-alcohol), is worthy of note. *Blutalkohol* is published by Steintor-Verlag, Lübeck and the first volume appeared in 1962/63. This periodical contains a wealth of information about forensic aspects of alcohol with direct relevance to the defense and prosecution of DUI suspects. Although most of the articles are written in German, English summaries are provided.

14.1.1 General Challenges

14.1.1.1 Drinking after the Offense

A frequent defense tactic is one in which the suspect claims to have consumed alcohol after driving or being involved in an accident such as a single-vehicle crash; this approach is sometimes called the hip-flask ploy.^{23,24} Prosecution for DUI must necessarily relate driving with the consumption of alcohol at a time before or during the driving. In these cases however it is alleged that the drinking took place after the driving, but prior to obtaining a specimen of blood or breath for forensic analysis. For example, hit-and-run drivers often manage to drive home. When eventually apprehended by the police, they might claim to have been sober during the driving but

needed alcohol to “calm their nerves” or alleviate the condition of shock caused by “hitting a bird or cat,” and the resulting damage to the car. Subjects will often insist they drank alcohol after driving, even when they cannot produce any empty or opened bottle of liquor or any other credible evidence such as eye witnesses to support their story. Some of the more experienced DUI offenders, especially repeat offenders, may carry a bottle of alcohol in their coat pocket or glove compartment, for the express purpose of being able to drink after driving; hence the origin of the term hip-flask defense. In some jurisdictions the prosecutor must prove beyond a reasonable doubt that the allegation of drinking after the offense was untrue, or that in spite of the alcohol consumed after driving the suspect’s BAC or BrAC at the time of driving still exceeded the legal limit. This is often a difficult task.

To deal with alleged drinking after the offense, the prosecutor has several options available and should seek help from qualified forensic experts when preparing the case. First, it is important to consider the testimony of the police or other witnesses who might have observed the actual driving, or the behavior and general appearance of the suspect when arrested. Such observations as the smell of alcohol on the breath, slurred speech, or unsteady gait are important to document before the driver has had the opportunity to drink any more alcohol. In cases where the subject has allegedly consumed a large quantity of alcohol immediately before being apprehended by the police, one would also expect to see a dramatic and progressive onset of symptoms of intoxication. Second, information regarding the quantity of alcohol allegedly consumed after driving, the time of intake and the sex, age, height, and body weight of the suspect can be used to calculate the expected BAC.²² If this approach is used, the suspect should be given the “benefit of any doubt” by assuming that at the time of sampling blood and breath, absorption and distribution from the post-incident ethanol consumption was complete.

The Widmark equation (see Chapter 5.2) is commonly used to calculate the expected BAC on the basis of the person’s body weight and drinking pattern.^{25,26} Making an adjustment for elimination of alcohol through metabolism between the time of starting to drink and the time of sampling blood is usually warranted, especially when several hours have elapsed between the time of the driving and the time of obtaining a blood-sample. In this way, a theoretical mean BAC and its 95% confidence interval can be compared with the analytical report from the forensic laboratory. The resulting difference in BAC, if any, should reflect the BAC that existed prior to the post-incident drinking, and therefore the BAC before or during driving. The use of a 95% confidence interval is a safeguard to allow for inter-individual variations in absorption, distribution, and elimination patterns of alcohol (see Chapter 5.2 for details). Grossly exaggerated claims of the amount of alcohol consumed after the offense, such as drinking a whole bottle of liquor in a relatively short time span, are clearly unrealistic and should be given little credibility.

The limitations of urine alcohol concentration (UAC) are dealt with in the next section; however, if the police manage to obtain samples of urine and blood shortly after driving, the magnitude of the UAC/BAC ratio can help resolve whether alcohol was ingested within approximately 1 h of taking the samples. This approach was tested empirically by Iffland et al.²⁷ who found that UAC/BAC ratios between 1.0 to 1.15 indicated fairly recent drinking whereas ratios larger than 1.2:1 indicate that the drinking began much earlier. This fits with the observation that during the absorption phase of alcohol kinetics, before equilibration has been reached, UAC is generally less than or equal to BAC. In the post-absorptive phase of alcohol metabolism, UAC is usually 1.3 to 1.5 times higher than BAC.^{28,29} The concentration of alcohol in pooled bladder urine mirrors the average concentration prevailing in the blood during the formation of urine in the kidneys and storage in the bladder.²⁸ Because urine has about 20% more water than an equal volume of whole blood, the concentration of alcohol in newly secreted urine is about 20% higher than BAC and a urine/blood ratio of 1.2:1 should be expected. Dividing the measured UAC by 1.2 gives an estimate of the lowest BAC at the time of voiding or since the bladder was last emptied. Moreover, a UAC/BAC ratio exceeding 1.3 suggests that the bulk of the alcohol was already absorbed into the blood and distributed throughout total body water. Whenever the police suspect that a person will

assert consumption of alcohol after driving, efforts should be made to obtain two specimens of urine about 30 to 60 min apart. If the UAC of the second void is higher than the first void then it seems reasonable to assume that absorption of alcohol from the stomach is not complete at the time of sampling. Such a finding would support the claim of recent consumption of alcohol. If the UAC decreases between the first and second void 30 to 60 min later, this suggests that the post-absorptive phase has become well established and the main part of the alcohol was imbibed at least 1 to 2 h earlier.^{28,29}

If the ratio of UAC/BAC is less than or close to unity, this supports the contention of recent consumption of alcohol and the BAC curve was probably still rising, or near the peak. If an alcohol-free pool of urine existed in the bladder before drinking started, this would tend to dilute the concentration of alcohol in primary urine secreted into the bladder and might suggest a rising UAC between the two successive voids, even though in reality the BAC curve was in the post-peak phase. Alternatively, evaluating the change in BAC between the times of taking two blood samples 30 to 60 min apart gives a good indication of whether a rising or falling BAC existed at the time of sampling.³⁰

Forensic toxicologists in Germany have developed another way to deal with allegations of drinking after the offense and this method has become known as congener analysis.^{31–34} In brief, this method entails analyzing the alcoholic beverage the suspect claims to have consumed after driving with the aim of identifying other volatile constituents besides ethanol. Pure ethanol does have a distinctive odor, although these other congeners (non-ethanol volatiles) produced during the fermentation process help impart the distinctive smell and flavor to the drink.³¹ The results of the congener analysis are then compared with the volatiles present in a sample of blood or urine taken from the suspect in an attempt to match the components. Methanol, 1-propanol, 2-butanol, and 2-methyl-1-propanol are typical examples of congener alcohols that can be identified in body fluids depending on the particular kind of beverage consumed.³² The results of congener analysis, together with other information, has been accepted by the courts in Germany when dealing with hit-and-run drivers who frequently claim drinking after the offense.^{31–34} The usefulness of analyzing methanol as a congener in forensic casework is limited by the fact that this alcohol is produced naturally in the body and its concentration in body fluids increases after ingestion of ethanol because of competition for the metabolizing enzyme alcohol dehydrogenase.^{35–37} Furthermore, if the beverage consumed before the incident is the same as that allegedly consumed afterwards, the congeners will be the same and this approach would not work.

Claims of drinking after the offense can be counteracted by appropriate legislation. For example, in Norway it is a separate offense for a motorist to consume alcohol within 6 hours of driving if there is good reason to believe that the police will want to investigate some event related to the driving. Thus, drinking within 6 h of an accident to reach a BAC in excess of the legal limit carries the same penalty as being found guilty of drunk driving (Norwegian traffic law, paragraph 22). Without this kind of legislation, the magnitude of the UAC/BAC ratio and the change in BAC between successive samples, or UAC between two successive voids, provides useful information to evaluate whether or not a person has consumed alcohol within an hour or so before taking the samples. Knowledge of the stage of alcohol kinetics is important not only in cases of alleged drinking after the offense but also when asked to engage in retrograde extrapolation of BAC to an earlier time. Accurate back-tracking of BAC to the time of driving is fraught with difficulties, and only an approximate result, and likely range of values is possible, based on known population averages for rate of alcohol elimination. Again, the need to back extrapolate can be avoided by statutory definition of the relevant BAC for prosecution as that existing at the time of sampling or within 2 to 3 h of the driving.

14.1.1.2 Laced Drinks

The “laced drinks” defense is another challenge that arises during prosecution of drunk drivers in their attempts to avoid punishment for DUI.^{17,19–21} The usual story is that a friend or associate

has added liquor (usually vodka) to a non-alcoholic drink or to beer when the person concerned was otherwise engaged or distracted. Another spin on this scenario is where the suspect has been invited to consume some kind of homemade beverage which was not recognized as containing a high alcohol content because the taste was masked by strong fruit flavoring. Unintentional intoxication through the over-consumption of alcohol-containing chocolates or alcohol-soaked fruit have also been documented. Only later, after being apprehended for DUI, was it apparent to the people in these cases that the drink must have contained an unusually high concentration of alcohol, which was not obvious from the taste. The subjective intoxication effects of alcohol differ widely among different individuals and this allows the defendant to argue that he or she was driving with a BAC above the limit but without intent, which although not a complete defense, may have some mitigating value.

Widmark calculations (see Chapter 5.2) are commonly used to estimate the BAC expected from the amount of alcohol inadvertently consumed in the laced drink.^{24,25} However, relating a given BAC to a precise degree of intoxication is difficult because of the wide variations in consumption and concentration tolerance between different individuals. Dram-shop laws in the U.S. place responsibility on the host at the party, or the owner of the bar for damages caused by a drunk driver if that person was served alcohol while he or she was visibly intoxicated.¹⁷⁻²² In a well-documented laced drinks case, a woman was acquitted after driving with a BAC of 0.17 g/dL. She admitted drinking from a "punch bowl" when visiting the home of some friends, although she denied knowledge of the fact that the drink was laced with 96% v/v ethanol, and claimed not to feel any definite impairment effects of alcohol despite the high BAC. The medicolegal experts called by the court refused to state with certainty that the woman must have felt under the influence of alcohol at a BAC of 0.17 g/dL. On appeal to the high court, the woman was acquitted of willfully driving under the influence. The prosecutor approached the supreme court but permission to review the case was refused.³⁸ The trend toward introducing lower legal limits and zero tolerance laws for young people should make the laced drinks defense, and thus driving over the limit without intent, a much more common defense tactic. This follows because of the great difficulty in recognizing symptoms of intoxication at very low BAC levels such as 0.02 g/dL where impairment may be minimal. The same applies to driving in the morning following an evening of heavy drinking, when low per se illegal concentrations of alcohol are enforced.

14.1.1.3 Rising Blood-Alcohol Concentration

Some DUI suspects argue that their BAC or BrAC was below the legal limit at the time of driving, but that the concentration of alcohol had risen to exceed the legal alcohol limit at the time of obtaining the samples for analysis. In short, if the prosecution BAC was 0.12 g/dL at the time of the test, it might be suggested that it was below 0.08 g/dL at the time of driving some time earlier.^{39,40} The key question here is by how much can the BAC or BrAC rise after the last drink? To answer this question, details of the subject's drinking pattern before or during the driving, as well as the various time elements and intake of food, should be carefully investigated. The pharmacokinetics of alcohol show large inter-individual variations especially when small doses are taken after a meal.^{41,42} This challenge is known as the rising BAC defense and the usual scenario according to the defendant is that he or she was engaged in moderate social drinking for several hours after work, perhaps with a meal or eating bar snacks. For some unexplained, and physiologically improbable reason, the alcohol ingested during the evening remained unabsorbed in the stomach until the person decided to leave for home or drive to the next bar. Shortly after driving the person is either involved in a collision or pulled over by the police because of a moving traffic offense, and in this connection is arrested for DUI. The defendant then claims that between the time of being apprehended and the time of providing the blood or breath-alcohol test, the alcohol in the stomach became absorbed into the blood, bringing the person over the legal limit.

Obviously, this scenario is unreasonable because alcohol, unlike many other drugs, starts to become absorbed from the stomach immediately following ingestion. Gastric emptying accelerates this process and leads to a rapid onset of the effects of alcohol on the brain. Indeed, people indulge in drinking primarily to experience alcohol's enjoyable pharmacological effects such as euphoria, relaxation, and diminished social inhibitions. In order for this to happen, the alcohol must become absorbed into the bloodstream and transported to the brain. The intoxicating effects of alcohol are more pronounced during the rising limb of the BAC profile, and people would surely be surprised if they had been consuming drinks for several hours without experiencing any effect! Unfortunately, only a handful of studies have looked at the pharmacokinetics of alcohol under real-world drinking conditions to establish, for a large number of subjects, the degree of rise in BAC and the time needed to reach the peak after the last drink.

Gullberg⁴³ reported a study in which 39 subjects drank various quantities of alcohol under real-world drinking conditions. The mean time required to reach the peak BAC after end of drinking was 19 min (span 0 to 80 min) and 81% of subjects reached a peak within 30 min. A study reported by Shajani and Dinn⁴⁴ also gives a clue to the time needed to reach peak BAC under social drinking conditions. In 8 men and 8 women who consumed known amounts of alcohol according to choice, the maximum BAC was reached 35 min (span 17 to 68 min) after end of intake. Taken together these studies and a few others suggest the low probability that the result of a blood or breath-alcohol test made some time after driving will be higher than at the time of driving which is often 1 to 2 h earlier. Zink and Reinhardt⁴⁵ made an important contribution when they allowed heavy drinkers to consume very large amounts of alcohol over periods of 6 to 10 h, resulting in peak BAC's in the range 0.10 to 0.38 g/dL. Venous blood was taken for analysis of alcohol at 15 min intervals during and after the drinking spree. In this way accurate information was obtained about the shape of the concentration-time profile and the time of reaching the peak as well as rise in BAC after the last drink. Importantly, they found that half the individuals had reached their peak BAC even before the last drink was taken (i.e., the rate of elimination exceeds the rate of consumption). The longest time necessary to reach a peak was 50 min after end of drinking (mean \pm SD, 7.7 ± 22.9 minutes), and when a rise in BAC occurred between the end of drinking and the peak BAC it was invariably less than 0.02 g/dL. This study has important ramifications because many DUI suspects have blood-alcohol concentrations in this high range when they are apprehended.

Drinking alcohol together with a large meal was studied by Jones and Neri⁴² who found that under these conditions, although the peak BAC was attained soon after the end of drinking for most subjects, a BAC plateau developed, and for some the BAC remained fairly constant for 2 to 3 h. Interestingly, in 10 of these subjects, 70% of the peak BAC had been attained within 15 min after the end of drinking. More studies are needed delineating the absorption kinetics of alcohol for different drinking conditions, with different beverages and formulations and with fast and slow ingestion of alcohol, on an empty stomach and after a meal.

Although a person's BAC or BrAC at the time of driving or when a road-traffic accident occurred might be considered the most relevant result for prosecution, it is fairly obvious that estimating this value can involve much uncertainty. This follows because the blood or breath-test is often made 1 to 2 h after the driving and there is a wide variation in absorption, distribution, and elimination patterns of alcohol in individual DUI suspects. Much can be gained by statutory definition of the relevant BAC or BrAC as that prevailing at the time of the chemical test and not at the time of driving. Unfortunately, many jurisdictions persist with using the BAC or BrAC at the time of driving as the relevant figure needed for prosecution of DUI suspects. Other jurisdictions accept the chemical test result, provided it was obtained within 2 h of the driving, as being equivalent to the BAC at the time of driving. Samples of blood or breath taken outside this time frame require the prosecution to estimate the BAC or BrAC prevailing at the time of driving. This entails making a back extrapolation of BAC from time of sampling to the time of driving and this calculation is always subject to much uncertainty. In cases where the statutory period of 2 or 3 h between the

driving and the time of the test is exceeded, error in back extrapolation can be minimized (in the defendant's favor), by only extrapolating back to the end of the 2- or 3-h period.

Provided the subject was in the post-peak phase of alcohol absorption-distribution at the time of driving and at the time of sampling blood, extrapolating back with a conservative alcohol burn-off rate, such as 0.008 to 0.010 g/dL per hour, can be defended. Other safeguards against overestimation include an adjustment for absorption of alcohol contained in the last drink, and allowing for the possibility of a BAC concentration plateau existing, during which time the BAC remains more or less constant for several hours, as sometimes happens if alcohol is ingested together with a large meal. Other reasonable approaches include the use of population mean elimination rates, with 95% confidence intervals to establish the most likely upper and lower limits of BAC.

A recent study of double blood samples from 1090 DUI suspects arrived at a mean alcohol burn-off rate of 0.019 g/dL per hour with 95% limits of agreement, spanning from 0.009 to 0.029 g/dL/h.⁴⁶ These results suggest that making a back estimation of a person's BAC over long periods of time and assuming a relatively low and constant burn-off rate such as 0.008 to 0.01 g/dL/h will lead to a large underestimate of the BAC at the time in question, but always in the defendant's favor. While this approach gives a definite advantage to the suspect, the practice of making a back estimation of a person's BAC is inevitably a controversial issue in DUI litigation and should be avoided whenever possible.^{47–50}

14.1.1.4 Pathological States and Ethanol Pharmacokinetics

The pharmacokinetics of many prescription drugs have been carefully investigated in patients suffering from various diseases.^{51–53} Much less work has been done concerning the influence of disease states on absorption, distribution, and metabolism of the social drug ethanol. DUI suspects sometimes claim however that they suffer from certain medical conditions or pathological states, which they hope might explain their BAC being above the legal limit for driving. Various claims of this kind have been documented such as liver cirrhosis, kidney failure, or absence of a kidney or one lobe of the lung. Because only 2 to 5% of the total quantity of alcohol consumed is excreted in urine and breath, reduced efficiency of the lungs or kidney has marginal effect on the total amount of alcohol eliminated from the body. The rate of alcohol elimination from blood in patients with kidney failure scheduled for hemodialysis was no different from the burn-off rate in healthy control subjects.⁵⁴

Major surgery to the gastro-intestinal tract, such as gastrectomy, is known to cause a more rapid absorption of alcohol leading to an overshoot peak, which tends to be somewhat higher than the maximum BAC expected.^{55–57} A similar phenomenon is often observed when drinking neat liquor on an empty stomach.⁴¹ However, 1 to 2 h after drinking ends, the BAC should approach the value expected for the dose of alcohol ingested and the person's gender and body weight because alcohol has now had sufficient time to equilibrate in the total body water. The rate of absorption of alcohol shows wide inter-individual variations even in apparently healthy individuals, and estimating the peak BAC from amount consumed is subject to considerable uncertainty.⁴¹ Jokipii⁵⁸ devoted his thesis work to comparing blood-alcohol profiles under controlled conditions in healthy subjects and in those with various diseases (liver cirrhosis, acute hepatitis, hyperthyreosis, diabetes mellitus, and neurocirculatory asthenia or dystonia). This publication is unfortunately not widely available, although its salient features were reviewed with the conclusion that these particular pathological states did not cause distorted alcohol burn-off rates or abnormal distribution volumes of ethanol compared with healthy control subjects.⁵⁹

Drunk drivers with de facto diseased liver, such as alcohol hepatitis or cirrhosis, insist that this renders them slow metabolizers of ethanol compared with individuals having normal liver function. Controlled studies of the effect of various liver diseases on the rate of disappearance of alcohol from blood are rather sparse. Ethical issues preclude embarking on detailed investigations of this topic. Those few studies available do not support the notion of a slower rate of metabolism outside the limits of 0.009 to 0.025 g/dL/h seen in healthy individuals.^{60–63} Moreover, results of alcohol

drinking experiments in patients with cirrhosis are often confounded by the problem of malnutrition in these binge drinkers. This also leads to a slower elimination rate of alcohol from blood.^{52,63} In patients with cirrhosis and severe portal hypertension, where part of the blood is forced to bypass the liver, there is some evidence to suggest a slower rate of ethanol disappearance (0.007 g/dL/h). The reason for this finding is probably diminished flow of blood to the alcohol metabolizing enzymes, and not so much necrosis of the liver tissue.⁶⁴

People suffering from chronic liver disease often accumulate a fluid in the peritoneal cavity called ascites.^{65,66} Indeed, ascites is one consequence of long-term abuse of alcohol and alcohol-induced cirrhosis. Because the ascites fluid is mainly water, this furnishes a body fluid reservoir for ethanol, thus increasing the person's volume of distribution. The volume of ascites fluid can vary widely between different individuals, and up to 5 liters is not uncommon. An increased total body water in patients with ascites raises the volume of distribution for other hydrophilic drugs besides ethanol. The concentration of alcohol in ascites will be closer to the concentration in plasma and serum than in whole blood. When alcohol has been cleared from the blood circulation the pool of alcohol in the ascites fluid can redistribute back into the bloodstream. However, alcohol cannot concentrate in this fluid space and ascites fluid should therefore contain approximately 10 to 20% more alcohol than an equal volume of whole blood. Like the situation with urine (see Chapter 5.2), there should also be a time-lag in the clearance of the alcohol from ascites fluid compared with blood.

Most of the scientific evidence indicates that alcoholics generally tend to metabolize alcohol faster than moderate drinkers owing to induction of the microsomal enzyme denoted P4502E1, and one of the consequences of long-term heavy drinking.⁶⁷ In a recent study in alcoholics undergoing detoxification with initial BACs of 0.20 to 0.45 g/dL, the burn-off rate (β -slopes) ranged from 0.013 to 0.036 g/dL/h with an average of 0.022 g/dL/h.⁶⁸ A similar mean value was reported when the work of several research groups based in Germany were compiled together; average elimination rate 0.022 ± 0.005 g/dL/h (mean \pm SD).⁶⁹ Many DUI suspects are clearly alcoholics, and in a study of 1090 apprehended drunk drivers from whom two blood samples were taken 60 min apart, the mean β -slope was 0.019 g/dL/h with 95% limits of agreement of 0.009 to 0.029 g/dL/h, being in close agreement with values for alcoholics during detoxification.⁴⁶

Individuals suffering from diabetes mellitus with impaired glucose metabolism might have elevated concentrations of ketone bodies, including acetone, circulating in their blood. Note that the acetone produced can also become reduced to isopropanol in the liver through the alcohol dehydrogenase pathway.⁷⁰ However, when modern gas chromatographic (GC) methods are used for blood alcohol analysis, acetone and isopropanol are easily distinguished, so defense challenges directed at the lack of specificity of GC methods are therefore pointless if two or more different stationary phases are used for the chromatography.⁷¹ There is no evidence to suggest that the rate of ethanol metabolism should be any different in people suffering from diabetes compared with healthy control subjects.^{72,73} The metabolic disturbances associated with insulin-dependent diabetes are not related to the enzymes involved in the disposal of ethanol.⁷⁴ Total body water and activity of alcohol dehydrogenase enzymes decreases in states of malnutrition and protein deficiency, and this is reflected in slower burn-off rates of alcohol.^{75,76} However, moderate losses of body water after prolonged sauna bathing did not result in any marked differences in the shape of blood-alcohol profiles.⁷⁷ A low relative TBW/kg body weight is associated with a smaller volume of distribution for ethanol and this explains the well known male-female difference in peak BAC and area under the curve for the same dose of alcohol administered per kg body weight.⁷⁸ The distribution volume of ethanol was shown to decrease in male subjects between the ages of 20 to 60 years along with a decrease in total body water in the elderly.⁷⁹

People involved in traffic accidents might be badly injured and suffer from shock and hemorrhage owing to massive losses of blood. This raises the question about the influence of trauma and shock on the hepatic metabolism of alcohol and the resulting blood-alcohol profiles.⁸⁰⁻⁸² In a recent study with 10 subjects involved in accidents when under the influence of alcohol, and suffering from poly-traumatic shock, a series of venous and arterial blood samples were obtained for

determination of ethanol.⁸³ The rate of alcohol disappearance from blood ranged from 0.017 to 0.021 g/dL/h (mean 0.018 g/dL/h) and these values were the same regardless of whether arterial or venous blood sampling sites were used. The results of this study confirm many other anecdotes and case reports regarding alcohol pharmacokinetics in people injured when drunk.^{80–82} Hypovolemic shock following massive loss of blood will result in a redistribution of body fluids and higher proportions of plasma enter the intravascular space to maintain an effective circulation and tissue perfusion.⁸⁴ This might alter the relative distribution of some protein-bound drugs and endogenous substances between body compartments, but the concentration of alcohol in the blood is not markedly influenced.^{85,86} Nevertheless, some people continue to speculate about the impact of trauma on blood-alcohol concentrations and alcohol burn-off rates, even though a careful review of the literature shows that there is no substance to these opinions.⁸⁷

14.1.1.5 Drug-Alcohol Interactions

The intake of various tonics (elixirs), cough syrups, over-the-counter medications, or even foodstuffs that might contain alcohol, will obviously result in alcohol appearing in the blood.⁸⁸ Some cough medicines, vitamin mixtures, pick-me-ups, and other health-store products may contain considerable quantities of alcohol (>10% v/v), and overdosing with these products will obviously elevate a person's BAC. By how much the BAC rises will depend on the quantities consumed and the time frame in relation to driving. Medication taken in tablet form or drugs applied externally can hardly be expected to lead to alcohol appearing in the blood. Psycho-pharmacological agents such as benzodiazepine derivatives may cause increased impairment when taken together with alcohol because of interaction at the GABA receptor complex in the brain.⁸⁹ However, there is no evidence to suggest that the resulting BAC will be any different from that expected if the same dose of alcohol had been taken without the drug.⁹⁰

Intake of alcohol can modify the pharmacokinetics and behavioral effects of drugs that are metabolized by P4502E1 enzymes or that interact with the GABA receptor to elicit their effects on the central nervous system.⁹¹ However, these changes do not result in an altered alcohol pharmacokinetics or a raised BAC above that obtained in control experiments when the same dose of alcohol was consumed on an empty stomach. One drug that does block the metabolism of alcohol is 4-methyl pyrazole (4-MP), which competes with ethanol for binding sites on the primary metabolizing enzyme ADH.⁹² However 4-MP is not prescribed by physicians even though it may have legitimate therapeutic uses in the treatment of patients poisoned with methanol or ethylene glycol.^{93,94}

14.1.1.6 Gastric Alcohol Dehydrogenase

The enzyme mainly responsible for the metabolism of alcohol is called alcohol dehydrogenase (ADH) and this is located primarily in the liver and to a minor extent also in other organs and tissue such as the kidney and the mucosa of the stomach.⁹⁵ Recent studies have shown that gastric ADH is seemingly less active in women compared with men and also in alcoholics compared with moderate drinkers, and the overall activity decreases with advancing age.⁹⁶ About 20 years ago the suspicion arose that part of the dose of alcohol consumed was metabolized in the stomach by gastric ADH. This process was known as pre-systemic metabolism or first-pass effect. This meant that the effective dose of alcohol reaching the systemic circulation depended on the efficacy of gastric ADH enzymes. Sex-related differences in gastric ADH offered another mechanism to explain why women reach a higher peak BAC than men for the same dose of alcohol.⁹⁷ If a part of the dose of ethanol is metabolized by gastric ADH, this would also explain the observation of a smaller area under the BAC-time profile after oral intake compared with intravenous administration of the same dose. Prolonged retention of alcohol in the stomach, such as after drinking together with or after a meal, allows more opportunity for pre-systemic oxidation by gastric ADH to occur.^{98,99}

Interest in the role played by gastric ADH in the overall metabolism of ethanol received a boost when *in vitro* studies showed that the enzyme extracted from gastric biopsies was inhibited by certain commonly prescribed drugs. Among others, aspirin and the H₂-receptor antagonists, ranitidine and cimetidine, used in the treatment of gastric ulcers and inhibition of secretion of excess stomach acid, were capable of blocking the action of gastric ADH.^{100,101} This led to the suggestion that people taking this medication, which is widely used in society, and now available without prescription, run the risk of obtaining higher than expected BAC's and, therefore, a potentially more pronounced impairment from the alcohol they consume.^{102,103} The drugs seemingly promote the bioavailability of ethanol by removing the potential for oxidation of some of the alcohol already in the stomach.^{102–104} Media coverage of this much publicized research triggered a large number of defense challenges from individuals who claimed to combine their H₂-receptor blocking drugs with intake of alcohol.¹⁰⁵ Studies purporting to show an enhanced bioavailability of ethanol, and a higher peak BAC from this drug–alcohol interaction were not very convincing. The number of volunteer subjects was often limited (N = 6) and very low doses of alcohol (0.15 to 0.3 g/kg) were ingested 1 h after a fat-rich meal. Moreover, the methods of alcohol analysis were not appropriate considering that the maximum BACs reached were only 0.015 to 0.025 g/dL, being far removed from the statutory limits for driving in most countries, namely, 0.05 to 0.08 g/dL.¹⁰⁶ Many subsequent studies involving larger numbers of subjects and a better experimental design failed to confirm the enhanced bioavailability of alcohol when H₂-receptor antagonist drugs were taken together with a moderate doses of ethanol 0.15, 0.30, or 0.60 g/kg.^{106–111} Accordingly, this defense challenge holds little merit to explain a person's BAC being above the legal limit for driving without intent. Many factors influence the rate of absorption of alcohol from the gut and the bioavailability, particularly the amount of food in the stomach before drinking.^{98,99} It is always good advice not to drink alcohol on an empty stomach.

14.1.1.7 Endogenous Ethanol and the Autobrewery Syndrome

With the help of sensitive and specific methods of analysis, very low concentrations of ethanol (0.5 to 1.5 mg/L) can be determined in body fluids from people who have not consumed any alcoholic beverages.^{112–114} It seems that endogenous ethanol (EE) is produced in the gut by microbes, bacteria and/or yeasts acting on dietary carbohydrates, but other biochemical pathways also exist according to a comprehensive review of this subject.¹¹⁵ Indeed, the existence of other metabolic precursors of EE was confirmed when ethanol was identified in blood and tissue samples from germ-free rats, because in these animals fermentation of carbohydrates by microflora inhabiting the gut cannot be invoked as an explanation.¹¹⁶ Because the portal blood draining the stomach and intestine must pass through the liver before reaching the heart, lungs, and systemic circulation, any EE formed in the gut is probably eliminated through the action of alcohol metabolizing enzymes located in the liver.¹¹⁷

Abnormally high (0.05 g/dL) concentrations of EE were measured in blood and cerebrospinal fluid from hospitalized patients who had allegedly abstained from drinking alcohol.^{118,119} The reports of this work were published in peer-reviewed journals, so these unusual findings give some cause for concern and warrant a carefully scrutiny. It seems that the methodology used for measuring ethanol in biological specimens was rather primitive involving wet-chemistry and oxidation, which is not a specific means of identifying ethanol. Whether dietary factors or even the medication prescribed to the patients were oxidized by the chemical reagents used in the assay, producing falsely elevated concentrations of EE needs to be explored.¹²⁰

If for some reason large quantities of ethanol are synthesized in the gastro-intestinal tract and overwhelm the capacity of the alcohol-metabolizing enzymes in the liver, then much higher concentrations of EE could appear in the peripheral venous blood. This is exactly what was described in a group of Japanese subjects who were suffering from various disorders of the gut. Some had previously complained of experiencing feelings of drunkenness even without consumption of

alcohol.^{121–122} This condition seemed to appear after the subjects had eaten a carbohydrate-rich meal, such as rice. This study from Japan was difficult to fault because ethanol was identified in blood, urine, and breath with the aid of a reliable gas chromatographic method used for quantitative analysis.¹²¹ The term used to describe this abnormal production of EE was “autobrewery syndrome” and to our knowledge this has been observed only in Japanese subjects.¹²³ It is widely known that the activity of alcohol metabolizing enzymes, especially aldehyde dehydrogenase, is diminished in Oriental populations compared with Caucasians, which might render Japanese and other Asians less able to clear ethanol from the portal blood.⁵⁹ Other requirements before “autobrewery syndrome” that should be seriously considered as contributing to a person’s BAC include genetic predisposition (Oriental origin), a past history of gastrointestinal ailments, documented medical treatment for the problem, low tolerance to alcohol, and reports of fatigue and drunkenness after eating meals.

The occurrence of EE has also attracted interest in clinical and diagnostic medicine as an indirect way to furnish evidence of yeast infections in the gut.¹²³ After obtaining a control pre-treatment blood sample, the fasted patient receives a 5 g glucose load orally and a second blood sample is taken again after 1 h. If the concentration of EE in the second blood sample is significantly higher than in the first, this indicates the possibility of a bacteria or yeast overgrowth in the stomach or small intestine causing a gut-fermentation reaction. Many studies from various countries have confirmed the existence of EE in blood and other biological media from healthy human subjects, but the concentrations rarely exceed 1.0 mg/L, which is over 1000 times less than the statutory BAC for unfitness to drive in most countries ($0.08 \text{ g/dL} = 0.8 \text{ g/L} = 800 \text{ mg/L}$). These vanishingly small concentrations lack any forensic significance except in exceptional circumstances such as that described for Japanese subjects suffering from gastrointestinal disorders (autobrewery syndrome).¹²¹ Concentrations of EE in blood samples from people with diabetes mellitus, as well as other metabolic disorders, were not much different from the values in healthy control subjects.¹¹³

14.1.2 Urine Samples

It has been known for more than a century that only a small fraction (about 1 to 2%) of the quantity of alcohol a person consumes is excreted unchanged in the urine.^{124,125} Indeed, collection and analysis of urine was recommended by Widmark as a chemical test to prove that a person had been drinking and as an aid in the clinical diagnosis of drunkenness.¹²⁵ When urine is used as a body fluid for analysis of alcohol in traffic law enforcement, great care is needed with the sampling protocol to ensure correct interpretation of results.^{28,29,126,127} This follows because the concentration of alcohol in urine does not relate to the concentration in the blood at the time of emptying the bladder.²⁹ Instead, the UAC reflects the average BAC during the time period in which the urine is being produced and stored in the bladder after the previous void.¹²⁸ During this storage time, the BAC might have changed appreciably and even reached a zero concentration. In the morning after an evening of drinking it is not uncommon to find that the first urinary void contains a relatively high concentration of alcohol, whereas blood or breath-alcohol content are below the limits of detection with conventional analytical methods.¹²⁹ The morning UAC reflects the person’s average BAC during the night after the last void before bedtime.

In the U.K. urine specimens were approved for evidential purposes after the Road Traffic Act of 1967, when an alcohol concentration of 80 mg/dl blood or 107 mg/dL urine was accepted as per se evidence of unfitness to drive safely.¹⁴ However, the rules and regulations required the collection of two samples of urine about 30–60 min apart.¹⁴ The first void empties the bladder of old urine, and the concentration of alcohol measured in the second void reflects the person’s blood-alcohol concentration at the mid-point of the collection period. Because urine contains about 20% more water than an equal volume of whole blood, the concentration of alcohol in the urine entering the ureter will always be higher than the concentration in blood flowing to the kidney.^{28,29} The urine/blood ratio in the post-peak phase of alcohol metabolism is about 1.33:1 on the average,

Table 14.1.1 **Evidential Breath-Alcohol Instruments Currently Used for Forensic Purposes in Europe and North America; the Statutory Limits of Blood-Alcohol (BAC) and Breath-Alcohol (BrAC) Concentration Are Also Reported**

Country	Breath analyzer	BrAC limit	BAC Limit
Sweden ^a	Evidenzer	0.10 mg/L and 0.50 mg/L	0.20 and 1.0 mg/g
Finland ^a	Alcotest 7110	0.22 mg/L and 0.53 mg/L	0.50 and 1.2 mg/g
Norway	Intoxilyzer 5000N	0.10 mg/L	0.20 mg/g
Great Britain	Intoxilyzer 6000	35 µg/100 mL	80 mg/100 mL
	Intoximeter EC/IR		
Ireland	Intoxilyzer 6000	35 µg/100 mL	80 mg/100 mL
Holland	DataMaster	220 µg/L	0.50 mg/mL
Austria	Alcotest 7110	0.25 mg/L	0.50 mg/mL
France	Ethylométer 679T	0.25 mg/L	0.50 mg/mL
U.S.A. ^b	Alcotest 7110	0.08 g/210 L	0.08 g/100 mL
	Intoxilyzer 5000 & 8000		
	Intoximeter EC/IR		
	DataMaster		
Canada	Intoxilyzer 5000C	0.08 g/210 L	80 mg/100 mL
	DataMaster C		
Germany	Alcotest 7110	0.25 mg/L	0.50 mg/g
Denmark	None at present	0.25 mg/L	0.50 mg/g

^a Sweden and Finland have a two-tier legal limit with more severe penalties for a DUI suspect with a high BAC.

^b In some U.S. states several different breath-alcohol instruments are approved for forensic purposes.

although large inter- and intra-individual variations exist.¹²⁸ Studies have shown that the urine/blood ratio of alcohol as well as its variability increases as the blood-alcohol concentration decreases.^{28,29} The mean ratio of 1.33:1 is higher than expected on the basis of water content differences (1.2:1), in part because of the time-lag between formation of urine in the ureter and storage in the bladder before voiding (see Chapter 5.2). With relatively short storage times the UAC/BAC ratio might be close to the value expected theoretically of 1.2:1. Note that in UK traffic-law enforcement, the DUI suspect's BAC is not estimated indirectly from the measured UAC. Instead, the legislature has adopted an alcohol concentration of 107 mg/dL in urine as being equivalent to 80 mg/dL in blood ($107/80 = 1.33$). This approach is similar to the way that the threshold limits of BrAC have been derived from the existing BAC, by dividing by the blood/breath conversion factor adopted by the legislature in the respective countries (see Table 14.1.1). Indeed, because of individual variations in the urine/blood and breath/blood ratios of alcohol, it is strongly recommended that UAC or BrAC not be converted into a presumed BAC as a measure of guilt in DUI prosecution. Instead, the threshold concentration of alcohol should be defined in terms of the substance analyzed whether this is breath or urine.^{15,16}

Not many jurisdictions allow the concentrations of alcohol determined in urine specimens as binding evidence for prosecution in DUI, especially when per se statutes operate. This caution is well founded if the measured UAC has to be translated into the presumed BAC because the urine/blood ratio is highly variable between and within individuals and also changes as a function of the BAC. However, unlike most other drugs, the UAC/BAC ratio is not influenced by diuresis because alcohol is handled by the kidneys exactly like water in a passive diffusion process.¹²⁶ Increasing the volume of urine excreted by drinking large volumes of water may dilute the urine as reflected by its osmolality and creatinine content but the concentration of alcohol in the specimen will remain unchanged.¹³⁰ One objection often raised against the use of urine-alcohol evidence in prosecution of DUI suspects is that some people cannot completely empty their bladders on demand. The retention of old urine with a higher content of alcohol than expected for the prevailing BAC at the time of voiding introduces uncertainty.¹³¹ The prevalence of urine retention in the population at large is hard to estimate although this problem is seemingly more common in elder men, and

some studies have detected as much as 25 mL of residual urine.¹³¹ However, the impact of urine retention on the concentration of alcohol determined in successive voids and the magnitude of error incurred if the UAC is converted into presumed BAC has not been demonstrated experimentally.

Because some people might have glucose in their urine,¹³² especially those suffering from diabetes mellitus,¹³³ there is always a risk that ethanol can be produced *in vitro* through the fermentation of sugar by micro-organisms or yeasts infecting the bladder or urinary tract.^{134,135} Some reports claim that ethanol can be produced in the bladder itself, so-called bladder beer.¹³⁶ This makes it important to include chemical preservatives such as sodium or potassium fluoride at a concentration of at least 1% w/v or sodium azide in the collecting tubes to inhibit microbial synthesis of ethanol.^{136,137} Storage of urine specimens in a refrigerator immediately after collection will also help to hinder the synthesis of ethanol through the action of *candida albicans* acting on glucose as substrate.¹³⁷

Some new research findings have demonstrated that production of alcohol directly in the bladder or in the collecting tubes *in vitro* after sampling can be detected by measuring in the urine the concentration of 5-hydroxytryptophol (5HTOL), a minor metabolite of serotonin.¹³⁸ The concentration of 5HTOL increases in blood and urine during hepatic oxidation of ethanol, so a normal concentration of 5HTOL in urine and an elevated concentration of ethanol suggest that the alcohol was synthesized after voiding from the action of bacteria or yeasts on carbohydrate or other substrates.¹³⁹

14.1.3 Blood Samples

14.1.3.1 Use of Alcohol Swabs for Skin Disinfection

Blood specimens collected for alcohol analysis in traffic law enforcement are generally taken from an antecubital vein with the aid of sterile equipment such as evacuated tubes (Vacutainer) or a disposable plastic syringe and needle. Preparation of the skin at the site of blood sampling with disinfectants such as ethanol (70% v/v) or isopropanol (70% v/v) should obviously be avoided if specimens are intended for clinical or forensic alcohol testing. Because sterile equipment is used, disinfection of the skin at the site of sampling is not really necessary and, instead, cleaning the skin with saline or soap and water is sufficient. Nevertheless, alleged contamination by ethanol or isopropanol in the swabs used to disinfect the skin is sometimes raised as a defense challenge in attempts to invalidate results of blood-alcohol analysis.^{140,141} Note, however, that the methods used for forensic alcohol analysis should be able to distinguish between ethanol and isopropanol.

Many studies have been done to evaluate the risk of carry-over of alcohol from the antiseptic used to swab the skin before the specimen of venous blood was taken for analysis.^{142,143}

A classic example of giving the benefit of the doubt was demonstrated when several hundred convictions for DUI in the U.K. were deemed invalid and the sentences overturned. This was felt necessary because the swabs normally issued with kits used for blood-sampling from DUI suspects had been inadvertently switched to another brand, which contained isopropanol.¹⁴⁴ The legal alcohol limit in the U.K. is 35 µg/100 mL breath and if the result is between 40 and 50 µg/100 mL the suspect can opt to provide a blood sample instead and the BAC is then used as evidence for prosecution (threshold BAC = 80 mg/100 mL). Because of reported large discrepancies between BAC and BrAC in this kind of paired test, the swabs used to clean the skin before drawing blood became suspect. This suspicion was strengthened when the swabs were shown to contain alcohol (isopropanol). This led to an official investigation. The convictions of several hundred individuals who had pleaded guilty to DUI and had received their sentences were considered unsound and quashed. It appears that this decision was reached by the court of appeals because the integrity of the blood specimen was cast in doubt, and the defendants were not aware of this when they were asked to plead guilt or not guilty to DUI. This led to several controlled studies into the risk of carry-over of alcohol from the swabs used to disinfect the skin. The results, however, showed that

contamination of the blood sample with various alcohols during venipuncture was highly unlikely and in most studies, only traces or no alcohol at all could be detected in the specimens.^{145–149}

If evacuated tubes are used for sampling blood, then two tubes should be filled with blood in rapid succession and gently inverted several times to mix with the chemical preservatives. If some coagulation does occur, the sample should be homogenized prior to sampling to prevent inadvertent aliquoting of the serum fraction which would contain more alcohol than a specimen of whole blood. The chemical preservatives are typically sodium fluoride (NaF), which prevents glycolysis and inhibits certain enzymes and micro-organisms that might be present in the blood, and potassium oxalate which serves as an anticoagulant. These substances are already in the tubes as supplied by the manufacturer, although the necessity of having sodium fluoride in sterile Vacutainer tubes is open to discussion because contamination with bacteria can, in reality, only arise from the skin at the point of inserting the needle. Nevertheless, NaF should be included if only to prevent this defense challenge from being raised; the amount of NaF recommended for blood specimens taken from living subjects is 100 mg/10 mL blood (1% w/v). If the amount actually present is challenged then methods are available to assay blood samples for fluoride ions such as by using ion-sensitive electrodes or by other means.¹⁵⁰ In the event that alcohol-containing swabs are used, the practice of always taking two tubes of blood for analysis has the advantage that any unusually large discrepancies in the results of BAC between the two tubes can be detected. If present, this might suggest carryover or some other problem. However, the studies from the UK cited above confirm several earlier reports, which demonstrated that the risk of carryover of alcohol, even when 70% ethanol was used as an antiseptic, is virtually non-existent.^{149,151} Another safeguard when filling evacuated tubes with blood is to remove each tube from the collecting needle and holder before withdrawing the needle from the puncture site.¹⁵¹

The concentration of alcohol in stored blood samples decreases on storage at 4°C despite the inclusion of 1% w/v NaF as preservative.¹⁵² The rate of loss of alcohol is only about 0.003 g/dL per month, and evidently occurs by a non-enzymatic oxidation reaction that involves oxyhemoglobin.^{152,153} If blood specimens are contaminated with microorganisms when the Vacutainer tubes are opened to remove aliquots for analysis, this can lead to a much more rapid disappearance of alcohol during storage compared with unopened tubes. It seems that various species of micro-organism utilize alcohol as a food.¹⁴⁰ Other considerations regarding specimen collection include filling the tube with as much blood as possible, to avoid having a large airspace. Volatiles, including ethanol, will accumulate in the headspace and will be lost when the tube is opened. In the event that a tube is opened and closed repeatedly, this could result in appreciable losses of alcohol.

The question of uptake of alcohol through the skin as a mode of entry into the body to produce elevated BAC has been raised as a defense challenge by people working with large volumes of solvents. In fact, the absorption of ethanol through the skin was investigated many years ago by Bowers et al.¹⁵⁴ in controlled experiments with several children and one adult. The legs of the test subjects were wrapped in cotton soaked in 200 mL of 95% ethanol and secured with rubber sheeting and sealed with adhesive tapes. Blood samples were taken before and at various times after this treatment but neither clinical signs of inebriation nor raised BAC were noted. It seems safe to conclude that ethanol cannot accumulate in the body, and BAC is not increased by absorption through intact skin.

14.1.3.2 Trauma and Intravenous Fluids

Drunk drivers are often involved in serious road-traffic crashes causing injury and sometimes death. Trauma resulting in massive losses of blood precipitate a hypovolemic shock and this requires swift emergency treatment. This might involve administering medication at the site of the accident such as pain killers and intravenous fluids to counteract shock and replace depleted body fluids. More intensive treatment can be given on arrival at a surgical emergency unit and it is usually at

this point that a blood sample is taken for clinical and/or medicolegal purposes. The sampling of blood for analysis of alcohol in a critically injured patient requires considerable deliberation to safeguard the integrity of the patient and the specimen. Errors incurred in sampling blood from trauma patients are not uncommon, and they are beyond the control of the forensic laboratory.¹⁵⁵ Care is needed if intravenous fluids are administered as a first aid for treatment of shock, and it is important that the blood sample for alcohol analysis is not taken downstream from the same vein used for infusion. Otherwise, this can result in a marked dilution of the specimen and a decrease in the concentration of alcohol. If dilution of the specimen is suspected, this can sometimes be verified by determination of hemoglobin.¹⁵⁵

Routinely analyzing aliquots of blood from two Vacutainer tubes that are filled in rapid succession furnishes a useful way to reveal discrepant results and problems associated with blood sampling. If the tube-to-tube difference in BAC exceeds that expected from knowledge of random analytical errors and past experiences, this points to other influences such as pre-analytical factors. Abnormally large differences in BAC between the two tubes can often be traced to dilution or coagulation of one or both of the samples because of inadequate mixing after collection. Note that the concentration of alcohol measured in plasma or serum will be higher than in whole blood by about 10 to 15% as discussed in detail elsewhere.¹⁵⁶

14.1.3.3 Blood-Water Content and Hematocrit

The water content of whole blood is easily determined by weighing an aliquot and heating overnight at 105 to 110°C to reach a constant weight.¹⁵⁶ The change in weight after desiccation can be used to calculate the water content of the blood specimen. According to the scientific literature whole blood contains 85 g water per 100 mL (95% range 83.0 to 86.5 g/100 mL).¹⁵⁷ The specific gravity of blood is 1.055 so the water content is 5.5% less when expressed in mass/mass units; 85.0% w/v corresponds to 80.6 % w/w.¹⁵⁷ Women tend to have approximately 1 to 2% more water than men for the same volume of whole blood owing to loss of red cells during periods of menstruation.¹⁵⁸

Whole blood is composed of a plasma fraction, red blood cells (erythrocytes), white blood cells (leukocytes), and platelets. Blood hematocrit is defined as the volume of packed cells per 100 mL of whole blood when expressed as a percentage. Normal values for hematocrit in men are 42 to 50% compared with 37 to 47% in women.¹⁵⁹ The red cells (erythrocytes) carry the hemoglobin and contain about 73 mL of water/100 mL cells whereas plasma contains 93 mL of water/100 mL plasma. Assuming a hematocrit of 40%, the water content of whole blood should be $(0.40 \times 73) + (0.60 \times 93)$ or 85 mL water/100 mL of whole blood. This value agrees well with gravimetric determinations of blood-water by desiccation and a mean value of 85.6% w/v was reported.¹⁵⁶ Because the red cells contain so much water and because alcohol distributes in blood according to the water content of the various components, it must be obvious that even fairly wide variations in hematocrit will not make much difference to the concentration of alcohol per unit volume of whole blood.

This was confirmed empirically when blood was prepared in-vitro with hematocrit values of 18, 31, 39, and 60.¹⁶⁰ The specimens were spiked with the same amount of ethanol to give a BAC of 0.212 g/dL and the actual concentration in each blood sample was determined by gas chromatography to be 0.211, 0.211, 0.207, and 0.208 g/dL respectively. Thus, no influence of varying hematocrit from 18 to 60 on the alcohol concentration in the whole blood was observed.¹⁶⁰ However, if equilibrated headspace vapor above the same blood specimens had been analyzed, the specimen with lowest hematocrit (large plasma portion and more water per unit volume) would have had a lower headspace concentration of ethanol compared with the specimens with higher hematocrit (low plasma portion and therefore less water content per unit volume).¹⁵⁸ This follows because the

concentration of alcohol in the vapor phase will be higher for the blood specimen with least water and therefore will contain a higher concentration of alcohol per mL blood-water.¹⁵⁸

A blood sample with abnormally low hematocrit means a low number of blood cells and also a low hemoglobin content, which might be associated with a patient suffering from anemia. The other extreme is polycythemia, which is an overabundance of red cells per unit volume of blood and therefore an abnormally high hematocrit in this condition. The question of whether variations in hematocrit influence the maximum BAC reached from intake of a known amount of alcohol is difficult to answer because large changes in hematocrit are often associated with changes in the distribution of body water in general and therefore with an altered volume of distribution for ethanol.¹⁶¹

14.1.4 Breath-Alcohol Analysis

Historical developments in testing for alcohol intoxication by use of chemical analysis of blood or breath were recently reviewed.¹⁶² Breath-tests for alcohol are currently used in forensic science practice and traffic law enforcement for two main purposes. The first and least controversial application involves roadside pre-arrest screening to furnish an objective indication of alcohol involvement and whether or not the driver might be above the critical legal limit for driving. In many situations, the police require probable cause before a chemical test for alcohol can be administered. This necessitates observations about the way the person was driving, and evidence of impairment from use of field-sobriety tests, which are important concerns before making an arrest and administering the chemical test for alcohol. Various hand-held devices are currently available for measuring breath-alcohol concentration at the roadside (Table 14.1.2). The most popular method of roadside breath testing involves the principle of electrochemical oxidation of alcohol with a fuel cell sensor and this technology is fairly selective because endogenous volatiles such as acetone and methane do not react with this kind of detector. However, if acetone is reduced in the body to isopropanol, this secondary alcohol is oxidized with the fuel cell sensor and can give a response that cannot be distinguished from ethanol.¹⁶³

The results of roadside breath-testing might be displayed as colored lights such as pass (green), warn (yellow), or fail (red), or as a digital display of breath-alcohol concentration in units such as mg/L or g/210L depending on the particular jurisdiction (Table 14.1.1). If the screening test gives a positive response this indicates the driver has been drinking and may be over the legal limit, which is sufficient probable cause to demand a specimen of blood or breath for evidential forensic analysis. The suspect is then taken to a police station where an evidential breath-alcohol test is conducted; examples of instruments used in various countries are given in Table 14.1.1. When properly calibrated and operated, the hand-held screening devices can be as accurate as any other breath test instrument. Some of the limitations of screening devices when used for quantitative

Table 14.1.2 Examples of the Most Commonly Used Hand-Held Breath-Alcohol Devices for Roadside Breath-Alcohol Screening Purposes and for Estimating the Coexisting Blood-Alcohol Concentration^a

Breath-test instrument	Method of alcohol analysis	Manufacturer and country
Alcolmeter SD-2	Electrochemical oxidation	Lion Laboratories, U.K.
Alcolmeter SD-400	Electrochemical oxidation	Lion Laboratories, U.K.
Alcotest 7410	Electrochemical oxidation	Dräger, Germany
Alcotest 6510	Electrochemical oxidation	Dräger, Germany
Alcosensor III and IV	Electrochemical oxidation	Intoximeters Inc., U.S.A.
Alcodoose II	Infrared Absorption (9.5 μ m)	Seres, France
Lifeloc FC10	Electrochemical oxidation	Lifeloc Inc., U.S.A.

^a To estimate BAC from BrAC, the breath analyzers must be pre-calibrated with a blood:breath conversion factor such as 2100:1 or 2300:1.

evidential purposes include: the lack of protection they provide against interference from mouth alcohol, the lack of blank tests or calibration control tests, the fact that they can generate low results at low temperatures, and also that for some older devices (Alcosensor III, Alcolmeter SD-2) the results are operator dependent; releasing the button before the reading has stabilized will generate a low result. Breath-alcohol instruments used for quantitative evidential purposes are generally more sophisticated than the hand-held screening devices and provide a printed record of results with date, time, location of the test as well as computer-storage of results for generating statistical reports. Moreover, these devices ensure that end-expired breath is being sampled and that residual alcohol in the mouth from recent drinking or regurgitation has not biased the result.

A critical element in performing an evidential breath-alcohol test is always to observe the suspect for at least 15 min before making the breath test. During this time he or she should not be allowed to drink, eat, smoke, or place anything in the mouth prior to completing the test. Moreover, a duplicate test should be made not less than 3 min and not more than 15 min after completion of the first test. The instrument calibration must be controlled in conjunction with testing the subject and this is accomplished with a breath-alcohol simulator device or alcohol contained in compressed gas tanks. Analysis of the room-air provides a blank test result before and between making the duplicate tests with the subject. All these requirements have been described in detail elsewhere and are important for ensuring a successful evidential breath testing program that will withstand scrutiny.¹⁶⁴ Regardless of these many new developments and improvements in the technology of breath-alcohol testing, challenges against the reliability of the results are far more common than against the results of blood-alcohol analysis. This probably stems from the fact that breath-testing is performed by police officers whereas blood-alcohol analysis is done at government laboratories by chemists, some of whom have research experience or a Ph.D. degree. Furthermore, the blood sample is usually retained and can be re-tested if there is any doubt about the results, whereas breath samples are generally not preserved and therefore cannot be re-tested.

14.1.4.1 Mouth Alcohol and Use of Mouthwash Preparations

Even during the first studies of breath-alcohol analysis as a test for intoxication, it was emphasized that testing should not be conducted too soon after the last drink.¹⁶⁵ Thus, Emil Bogen in his landmark article, which was published in 1927, made the following statement;

“As soon as the disturbing factor of alcoholic liquor still in the mouth is removed, which occurs usually within fifteen minutes after imbibition, in the absence of hiccuping or belching, the alcoholic content of 2 liters of expired air was a little greater than 1 cc of urine.”

A multitude of studies have been done since the 1930s to confirm the importance of a 15-min deprivation period after the last drink even though this problem is sometimes rediscovered from time to time.¹⁶⁶ Most experiments on the influence of residual mouth alcohol on breath-test results have generally involved human subjects initially alcohol-free who are required to hold solutions of alcohol (40% v/v) in their mouths for 1 to 2 min without swallowing.^{167,168} Immediately after expelling the alcohol, the test subject undergoes a series of breath tests at 1- to 2-min intervals for 20 to 30 min. The results show that within 15 to 20 min after ejecting a strong solution of alcohol from the mouth, the response of the breath-alcohol analyzer is always less than 0.01 g/210 L, which is generally considered the threshold for baseline readings. Other study designs have involved measuring breath-alcohol in subjects after they drink alcohol to reach a certain BAC level.¹⁶⁹ After rinsing the mouth with more alcohol, breath tests are made repeatedly until the results recover to the pre-drinking BrAC. Under these test conditions, the time needed to clear the residual alcohol from the mouth was even less than 10 min.¹⁶⁹

Accordingly, on the basis of experiments such as these, rules and regulations for evidential breath-alcohol testing stipulate a 15- to 20-min observation period before conducting an evidential

breath-alcohol test. During this time the suspect should not be allowed to smoke or drink or place any material in the mouth, and if he or she regurgitates or vomits, the observation period must be started again. Although a 15-min observation period is not mandated prior to conducting roadside breath-alcohol screening tests, in practice, a considerably longer time will usually have elapsed since the last drink was taken, unless the drinking took place while the person was driving. The time involved in stopping the vehicle, and contacting the driver, as well as any necessary field sobriety testing will usually take longer than 15 min. For reliable quantitative determinations, however, the 15-min deprivation period should be observed and documented.

Many mouth-wash preparations contain alcohol as well as other organic solvents, and the concentrations sometimes are as high as 50 to 60% v/v. Obviously the use of these materials prior to conducting a breath-alcohol test would produce similar disturbances on breath-test results as having alcoholic beverages in the mouth. Provided that the 15 to 20 min observation time is maintained, use of breath fresheners containing alcohol will not have any negative impact on the reliability of the test result.¹⁷⁰ However, if these preparations are intentionally or unintentionally consumed, this will be a source of alcohol just like drinking an alcoholic beverage. In a recent study with commercial mouthwash products, Listerine (29.6% alcohol), Scope (18.9% alcohol), and Lavis (6.0% alcohol), tests were made on a breath-alcohol analyzer after rinsing the mouth with these preparations. Within 2 min of rinsing the mouth, breath-test results were as high as 240 mg/dL (expressed as BAC equivalent) but within 10 min this had dropped dramatically and was well below the threshold limits for driving (0.08 to 0.10 g/dL). By 15 min post-rinsing, the readings were below 0.01 g/dL. Similar results, namely no significant response with an infrared breath-alcohol analyzer, were obtained 15 to 20 min or more after various mouthwashes, aftershave lotions, and perfumes in common use in Germany were tested.¹⁷¹

14.1.4.2 Regurgitation and Gastro Esophageal Reflux Disease (GERD)

The pioneer work by Bogen¹⁶⁵ indicated that hiccuping, burping, and belching might present a problem in connection with breath-alcohol analysis. Only very limited investigations of this problem have been made, and these indicate that the risk of elevating breath-alcohol readings is greatest shortly after the end of drinking as might be expected because the concentration of alcohol in the stomach is then at its highest.^{172,173} A closely related problem is gastro-esophageal reflux disease (GERD).^{174–177} Many people suffer from acid-reflux disorders, known as reflux esophagitis, whereby gastric secretions as well as other liquid contents erupt from the stomach into the esophagus and sometimes reach the mouth.^{178–180} Indeed, this condition might be aggravated after drinking certain alcoholic beverages.^{181,182} The impact of GERD on results of evidential breath-alcohol testing has not yet been investigated in any controlled studies. Nevertheless, this medical condition has been raised as a defense challenge from DUI suspects who maintain they experienced a reflux from the stomach into the mouth immediately prior to providing a breath-alcohol sample.¹⁸³ The higher the concentration of alcohol prevailing in the stomach during a reflux, the greater the risk of contaminating the breath-sample in a similar mechanism to the mouth-alcohol effect. From this follows the contention that GERD is the cause of a person's BrAC being above the legal limit for driving, and medical experts have testified to this effect, which has led to the acquittal of a DUI suspect.¹⁸⁴ However, the validity of this defense argument was strongly questioned by another expert as being one of the least convincing, and he also noted that the doctors appearing for the defense "ignored one of the basic maxims in the business," namely "what the subject says he has drunk is not evidence."¹⁸⁵

Although most evidential breath test instruments feature "slope detection" to disclose the presence of mouth alcohol, in some cases these may not detect small contributions resulting from belching or burping. A far better approach to counter the GERD defense challenge is always to observe the subject carefully, and to perform duplicate breath-alcohol analyses, that is two separate exhalations 3 to 5 min apart.¹⁸⁵ Obtaining close agreement between the two independent results

speaks against the influence of regurgitation of stomach contents having a high concentration of alcohol just prior to making the first breath-test or between the first and the second test. Also the risk of GERD elevating the breath test result decreases as the time after ingestion of alcohol increases because of the ongoing absorption of alcohol from the stomach and the emptying of the stomach contents into the duodenum. Evidential breath-alcohol programs that require only a single breath-alcohol test are out of date and should be abandoned especially if GERD is a recurring defense argument. The single chemical test for alcohol has no place in jurisdictions where per se statutes operate, regardless of whether blood or breath analysis is used for forensic purposes.

14.1.4.3 Dentures and Denture Adhesives

The question of people with dentures or individuals who might be fitted with special bridge-work where alcohol can be trapped has arisen as a possible cause of obtaining a falsely elevated breath-alcohol reading.^{186,187} This challenge is therefore akin to having residual alcohol in the mouth from recent drinking. The empirical evidence supporting the notion that sufficient alcohol becomes trapped under denture plates or in other structures or cavities in the mouth for long periods of time is not very convincing, although a few isolated case reports support this defense argument.¹⁸⁸ A person suspected for DUI in the U.K. was acquitted when expert testimony raised a reasonable doubt about the validity of the evidential breath test performed using an Intoximeter 3000 breath alcohol analyzer. Alcohol allegedly was trapped in cavities in the mouth as a result of dental treatment.¹⁸⁶ However, the experiments and reasoning presented to support this defense argument were speculative, not very convincing, and were easy to fault.¹⁸⁷ An acquittal in a DUI case in the U.S. was obtained when expert evidence suggested that the breath-test results were suspect because of alcohol being absorbed by the particular kind of denture adhesive used by the defendant.¹⁸⁸

The most convincing study appearing in a peer-reviewed journal dealing with breath-alcohol testing and the use of dentures involved the participation of 24 subjects.¹⁸⁹ They were tested under various conditions; with dentures intact, with dentures removed, and with dentures held loosely in place both with and without adhesives. The volunteers held 30 mL of 80 proof brandy in their mouths for 2 min without swallowing. After ejecting the alcohol, breath-alcohol tests were made with an Intoxilyzer 5000 instrument at regular intervals. After an elapsed time of 20 min, no results were above 0.01 g/210 L.¹⁸⁹ This argues convincingly against the idea of people who wear dentures obtaining falsely elevated breath-alcohol concentrations. The widely practiced deprivation period and observation time of 15 to 20 min seems adequate to eliminate the risk of mouth-alcohol invalidating results even in people with dentures.¹⁹⁰

A recent report described experiments in a person with dentures who was suspected of DUI. The defendant alleged that the brand of denture adhesive used was responsible for the breath alcohol reading being above the legal limit of 0.10 g/210 L breath.¹⁸⁸ In one set of tests with a Breathalyzer model 900, which is not equipped with a slope detector, prolonged retention of alcohol was observed remarkably for several hours after 86 proof whisky was held in the mouth and when a certain brand of dental adhesive was used. These results suggest that some kinds of denture adhesives might retain alcohol for longer and lead to false high breath-alcohol readings. However, no corroborative reports of this have been published, and more controlled studies are necessary making use of duplicate measurements of blood and breath-alcohol concentration, weaker solutions of ethanol, and monitoring the shape of the BrAC exhalation profile in order to substantiate these surprising observations and conclusions.

Many of the latest generation of breath-alcohol analyzers used for evidential purposes are equipped with a slope-detector mechanism, which is designed to monitor the time-course of BrAC during a prolonged exhalation.^{191,192} If the BrAC is higher at the start of an exhalation compared with at the end of the exhalation, this causes a negative slope and suggests a possible mouth alcohol effect or perhaps regurgitation of stomach contents or GERD. More work is necessary to evaluate

the effectiveness of the slope detectors fitted to evidential breath-alcohol analyzers over a wide range of concentrations of alcohol in the mouth, and at various times after the end of drinking.

14.1.4.4 Alleged Interfering Substances in Breath

The alleged response of breath-alcohol instruments to interfering substances is a common DUI defense argument in many countries.¹⁹³ The interferents in question are either claimed to have been produced naturally in the body, so called endogenous breath volatiles, or volatile organic compounds (VOC) inhaled with the ambient air during occupational exposure. The question of whether substances other than ethanol give a response on evidential breath-alcohol instruments escalated dramatically in the early 1970s after infra-red absorptiometry started to become the technology of choice for evidential purposes.¹⁹⁴ Hitherto, the Breathalyzer model 900 dominated the field of breath-alcohol testing in the U.S. and this device incorporates wet-chemistry oxidation with photometric endpoint for determination of BrAC.¹⁹⁵ Although this represents a non-specific chemical oxidation reaction for the analysis of alcohol, provided the galvanometer on the Breathalyzer was read after exactly 90 seconds as per the instructions, the presence of acetone, toluene and other substances in the breath do not present a serious interference problem.^{196,197} Most infrared evidential breath alcohol devices provide some control for the presence of interfering substances with the use of either multiple filters, or dual technology, such as electrochemical oxidation in conjunction with infrared.

Endogenous Breath Volatiles

Human expired air consists of a mixture of gases including oxygen, nitrogen, carbon dioxide, water, vapor, and in extremely small amounts a multitude of volatile organic compounds (VOCs).^{198–200} The major endogenous breath volatiles are acetone, methane, and the unsaturated hydrocarbon isoprene (2-methyl-1,3-butadiene).^{201–204} The concentration of acetone expelled in breath is usually between 0.5 and 5 µg/L but this can increase appreciably if a person is deprived of food or engages in a prolonged fast.²⁰⁵ Moreover, during ketoacidosis, a condition often associated with hyperglycemia, diabetes mellitus, or alcohol withdrawal, the concentration of ketone bodies (acetone, acetoacetate and beta-hydroxybutyrate) circulating in the blood increases appreciably along with the concentration of acetone expelled in the breath.^{205–208}

The question of whether VOCs other than ethanol might interfere with the results of evidential breath-alcohol testing started to become an issue of debate and concern shortly after the first Intoxilyzer instrument, a single wavelength (3.39 µm) analyzer, appeared for use in law enforcement.¹⁹⁴ The Intoxilyzer measures the C-H bond stretching and vibrational frequencies in ethanol molecules, which means that abnormally high concentrations of acetone (blood/air distribution ratio approximately 300:1) in breath becomes a major candidate as an interfering substance. However, this problem was quickly solved by monitoring the absorption of infrared radiation at two wavelengths such as 3.39 and 3.48 µm as currently used with the Intoxilyzer 5000.¹⁹³ Another approach to enhance selectivity is to incorporate two independent methods of analysis such as IR and electrochemical oxidation in the same unit as is used with the Alcotest 7110.²⁰⁹

When properly adjusted, the Intoxilyzer 5000 instrument corrects the ethanol signal for the presence of acetone in the breath. Moreover, if the concentration of breath-acetone exceeds 300 to 600 µg/L, corresponding to a blood concentration of 0.009 to 0.018 g/dL, the imbalance between the two filter signals exceeds a pre-set threshold value and the evidential test is aborted.¹⁹³ The instrument reports an interferant detected and the “apparent ethanol” concentration is stored in an internal memory of the software. If very high concentrations of acetone are present in the blood, this ketone can be reduced by alcohol dehydrogenase in the liver to produce isopropanol, which also absorbs infrared radiation at the wavelengths used and can masquerade as ethanol.¹⁶³ Methanol, which has highly toxic metabolites, presents a special problem if high concentrations are present in blood and breath because infrared breath-alcohol analyzers cannot easily distinguish this one-carbon

alcohol from ethanol if only two infrared wavelengths are used. The potential for methanol to interfere with a breath test can best be addressed by a consideration of its toxicological properties.⁹⁴

Isoprene is another endogenous VOC expelled in the breath. In experiments with 16 healthy subjects, the breath isoprene concentration ranged from 0.11 to 0.70 µg/L as determined by thermal desorption gas chromatography and UV detection.²⁰¹ These concentrations are much too low to interfere with the measurement of breath-alcohol with the infrared technology currently used for evidential purposes. Methane is produced in the gut by the action of colonic bacteria on disaccharides and this VOC can be detected in human expired air. It seems that some individuals are more prone than others to generate methane in the large intestine and the concentration of this hydrocarbon expelled in breath under different conditions requires more documentation.²⁰⁴ Methane should perhaps be considered as a potential interfering substance in connection with forensic breath-alcohol testing by infrared methods, but more research is necessary on this topic before raising an alarm.²⁰³

Acetaldehyde is a VOC produced during the metabolism of ethanol by all known enzymatic pathways and is also a major constituent of cigarette smoke. The high volatility and low blood/air partition coefficient of acetaldehyde (190:1) means that this substance crosses the alveolar-capillary membrane of the lungs and enters the breath.²¹⁰ Because acetaldehyde absorbs IR radiation in the same region as ethanol (3.4 to 3.5 µm) this VOC might be considered a potential interfering substance in connection with evidential breath-alcohol testing. This problem was investigated empirically in tests with a single wavelength (3.39 µm) infrared analyzer under conditions when abnormally high concentrations of breath-acetaldehyde (50 µg/L) existed.²¹¹ This was accomplished by inhibiting the metabolism of acetaldehyde by pretreatment of subjects with Antabuse-like drugs before they drank alcohol. Even under these extreme conditions, no false-high apparent ethanol readings were obtained. In recent reviews of the biomedical alcohol research literature, it seems that the concentrations of acetaldehyde in blood are very low during oxidation of ethanol (< 88 µg/L corresponding to 0.46 µg/L in breath) that this metabolite of ethanol cannot be seriously considered an interfering VOC when testing drunk drivers with the aid of infrared analyzers.^{210,212}

Occupational Exposure to Organic Solvents

A few studies have dealt with the response of infrared breath-alcohol instruments after occupational exposure to solvent vapors, although no convincing evidence of an interference problem has emerged, provided that at least 20 min elapses after leaving the work environment.²¹³ In an effort to investigate the claims from two convicted drunk drivers that inhalation of solvents caused false high readings on an infrared breath-alcohol instrument, the men volunteered to spray cars with toluene/xylene/methanol-based paint thinner under extreme working conditions and without the use of protective clothing or face masks.²¹⁴ They worked for several hours in a small poorly ventilated room making use of 5 to 7 liters of paint during this time. It was noted that their eyes were watering and they were suffering from severe irritation, coughing regularly and complaining of sore throats. Tests with one of the subjects gave measurable apparent ethanol responses during the exposure. Results with an infrared breath analyzer (Intoximeter 3000) were consistently higher than those obtained with an electrochemical instrument (Alcolmeter S-D2). At times of 0 min, 15 min, and 30 min after leaving the small working environment, one subject gave BrAC results of 0.019, 0.010, and 0.002 g/210 L on the IR analyzer. The lack of any instrument responses for the other subject was explained by a considerably lower environmental temperature on the day of the testing, and this presumably led to a less efficient vaporization of the solvents.

Inhalation of gasoline fumes as might occur if a person sniffs this liquid or engages in siphoning gasoline between cars can cause falsely elevated readings on the Intoxilyzer 5000.^{215,216} In an actual DUI case scenario, the Intoxilyzer reacted by aborting the test because an interfering substance or substances were detected.¹⁹³ Gasoline contains, among other things, a complex mixture of aliphatic and aromatic hydrocarbons and these were also qualitatively identified in a blood sample taken from the suspect whose blood-alcohol concentration was zero. Abuse of organic solvents such as

thinner or glue is another source of interfering substances in connection with evidential breath-alcohol testing.²¹⁷ People who abuse these materials often tend to smell of the solvents they inhale, and may display characteristic symptoms of intoxication. If there is evidence to suggest solvent abuse, or extended exposure to solvent fumes, arrangements should be made for obtaining blood samples instead.

Diethyl ether is another solvent capable of interfering with the response of dual wavelength infrared breath-alcohol instruments and being mistakenly reported as ethanol.²¹⁸ This solvent is no longer widely used in industry or hospitals, so the risk of being exposed to ether in everyday life is not very high, although it is present in carburetor or starting fluid. Several other case reports have appeared suggesting that work-related inhalation of toluene and lacquer fumes in conjunction with normal occupational exposure gives readings on IR analyzers exceeding 0.10 g/210L.^{219,220} However, the test subject who had been apprehended for DUI sometimes showed behavioral manifestations of solvent inhalation or abuse and was chronically exposed to these agents over a period of many years, so accumulation of toluene in body fat depots cannot be excluded. Some drunk drivers use technical spirits for intoxication purposes and these solvents contain ethanol, methanol, methyl ethyl ketone, ethyl acetate, and isopropanol as well as other VOCs. These substances absorb IR radiation and can be mistakenly identified as ethanol with some IR breath-alcohol analyzers.²²¹ By comparing the results from a pre-arrest roadside test utilizing an electrochemical sensor for ethanol determination, with the results from infrared evidential analyzers, useful information can be gleaned about the presence of an interfering substance. The two detector systems (IR and Fuel cell) respond differently to different VOCs in the breath; electrochemical sensors don't respond to acetone or hydrocarbons.^{222,223}

A comprehensive series of experiments on the subject of evidential breath-alcohol testing and the response to organic solvents was made in the U.K., where two infrared analyzers have been used for legal purposes since 1983.^{224–226} Human volunteers were exposed on different occasions to toluene, 1,1,1-trichloroethane, butane, white spirit, and nonane under controlled conditions, and blood and breath were sampled at regular intervals after ending the exposure. The volunteers assumed a resting position talking and playing cards during a 4-h period of exposure to the solvents at concentrations close to the upper limits prescribed for the workplaces in the U.K. After inhalation of butane vapor a response was seen on the infrared breath analyzers lasting for 1 to 5 min after exposure, before rapidly declining to zero.²²⁴ Exposure to toluene and 1,1,1-trichloroethane did not give any response on the IR analyzers although these substances were identified in blood samples for up to 8 h after exposure ended.²²⁴ The concentration of the solvents in blood and breath decreased rapidly on ending the exposure, which supports the conclusion that normal occupational use of solvents would be unlikely to contribute to false high results on IR breath-alcohol analyzers. Similar negative findings on evidential breath-test results were reported after inhalation of nonane and white spirit.²²⁵

Elevation of blood and breath-alcohol concentrations as a result of inhalation of ethanol vapors by brewery or distillery workers or industrial workers required to handle ethanol-based solvents has been a recurring argument in DUI trials.²²⁷ One of the first controlled studies was done in 1951 with subjects being exposed to varying concentrations of ethanol vapor for up to 6 h.²²⁷ The results showed that alcohol could be absorbed into the blood by inhalation through the lungs, and that the BAC attained was proportional to the concentration of ethanol in the inhaled air and the rate of ventilation. However, extreme conditions were necessary to build-up a BAC exceeding 0.01 g/dL, and the methods of blood and breath-alcohol analysis were fairly primitive.²²⁷ Note that between 6 to 8 g of ethanol can be metabolized per hour so uptake by inhalation and absorption through the lungs must exceed this amount before the BAC will increase above base-line levels. Moreover, it was noted that inhalation of air-alcohol concentrations of 10 to 20 mg/L caused coughing and smarting of the eyes and nose. Untoward effects were more pronounced at concentrations of 30 mg/L, and at 40 mg/L the situation was barely tolerable, making it impossible to remain in this atmosphere for any length of time.

Several more recent studies have looked in theory and practice at the reality of generating an elevated BAC from inhalation of ethanol vapor.^{228–230} From these experiments we conclude that obtaining a BAC exceeding 0.003–0.005 g/dL is highly unlikely as a result of normal occupational exposure owing to the metabolism of ethanol that occurs during and immediately after ending the exposure.²³¹ However, if a person already has an elevated BAC before entering an atmosphere with a very high alcohol vapor concentration (simply sitting in a bar is not sufficient!), then the metabolism of alcohol and clearance of BAC might be delayed during the inhalation period. This would lead to a shallower β -slope than expected if the intake of alcohol by inhalation is sufficient to balance the amount eliminated by metabolism.²³² In short, caution should be exercised in interpreting breath test results from subjects with extensive solvent exposure immediately prior to the breath test. Most solvents are rapidly distributed and eliminated following environmental exposure. There is no evidence that casual exposure to solvents or solvent-containing products will exert an effect on an evidential breath test administered an hour or more later.

14.1.4.5 Variability in the Blood/Breath Alcohol Ratio

Historically, the first breath-alcohol instruments were developed and used as an indirect way of measuring a person's blood alcohol concentration. Breath-testing was considered more practical than blood-testing for traffic-law enforcement purposes,¹⁶² because of the noninvasive sampling technique and the fact that an immediate indication of the person's blood-alcohol concentration and state of inebriation were obtained.²³³ Conversion of a measured BrAC into the expected BAC was accomplished by calibrating the breath-analyzers with a constant factor (2100:1), which was known as the blood/breath ratio of alcohol. The figure of 2100:1 had been determined empirically by equilibration of blood and air at constant temperatures *in vitro* and also *in vivo* by taking samples of breath and venous blood at nearly the same time from a large number of volunteer subjects.^{234,235} In the post-absorptive phase of alcohol metabolism, studies showed that the blood/breath ratio of alcohol was approximately 2100:1, and this figure was subsequently endorsed by several meetings of experts with international representation.¹⁶² However, the blood/breath ratio is not a constant for all individuals and varies within the same individual from time to time and during different phases of alcohol metabolism.²³⁶ This variability needs to be considered when the results of breath-alcohol testing are used in criminal litigation to estimate a person's blood-alcohol concentration.

All analytical results have inherent uncertainty, resulting from a combination of human error, systematic errors in calibration, random instrument error, etc. In a forensic context, the extent of any error should be known by analysis of appropriate standards and controls, and the contribution of error or uncertainty in the measurement should be considered when the result is interpreted. When measurements are being made of dynamic systems, such as exhaled human breath samples, further biological variation outside of the control of the analyst is introduced. The inherent variability in the blood/breath alcohol ratio among different individuals is an excellent example of this, and has emerged as a hot topic of discussion and debate in the scientific literature and in the courts.^{17–22}

For many years, the results of breath-alcohol analysis in law enforcement were overshadowed by inherent variations in blood/breath ratio and allegations that BAC had been overestimated by use of breath-test instruments. Obtaining an estimated BAC that was too high was more likely during the absorption phase, when BAC was still rising, because of the existence of arterial-venous (A-V) differences in alcohol concentration. The time course of breath-alcohol concentration follows more closely the arterial BAC than the venous BAC, with the arterial BAC exceeding the venous during the absorptive phase, and vice versa during the elimination phase. Moreover, the 2100:1 ratio was originally determined by comparing venous BAC and BrAC in samples taken during the post-absorptive phase of alcohol metabolism when A-V differences are small or negligible.²³⁴ The actual blood/breath conversion factor is clearly a moving target, and its value depends on many factors that are impossible to know or control in any individual subject at the time of testing. Several more recent studies comparing blood and breath-alcohol in DUI suspects show that in the field,

the blood/breath ratio is closer to 2400:1 with a 95% range from 1900 to 2900, indicating a strong bias in favor of the suspect being breath-tested in comparison with the same person providing a specimen of blood for analysis at a forensic laboratory.^{237–240}

In an attempt to quell much of the troublesome debate that was erupting over the continued use of a constant blood/breath ratio, experts in the field of chemical tests for intoxication met to discuss the scientific and legal issues involved. The fruits of this meeting came in the form of a signed statement endorsing the continued use of the 2100:1 ratio for clinical and forensic purposes. Several new studies verified that the 2100:1 ratio gives a generous margin of safety in favor of the subject by about 10% compared with venous BAC analyzed directly.^{241,242} In controlled laboratory studies, with blood and breath samples taken during the post-absorptive phase of alcohol metabolism, a blood/breath ratio of 2300:1 was more appropriate to give unbiased estimates of venous BAC.²⁴¹ To eliminate the entire problem of variability in the blood/breath ratio and the need to convert BrAC to BAC, Mason and Dubowski suggested that the threshold alcohol limit for driving should be defined in terms of the person's BrAC at the time of the test.²⁴² This approach was clearly similar to the use of UACs in Great Britain, where the statutory limits for motorists are 80 mg/dL in blood or 107 mg/dL in urine, which implies a UAC/BAC of 1.33:1.¹⁴ Because a blood-alcohol concentration limit of 0.10 g/dL was already widely accepted in the U.S., the corresponding threshold BrAC limit was set at 0.10 g/210 liters of breath. By including the 210 liters in the wording of the statute, the weight of alcohol (0.10 g) remained the same regardless of whether blood or breath-alcohol testing were used for analysis. Much is often made over these units given the fact that 210 L is a larger volume than any human could exhale. This is clearly a spurious issue, however, since only a portion of the breath (typically around 50 mL) is being tested, and the units used are g/210L. The results could equally well be expressed in µg/L, mg/mL, micromoles per liter, or any other concentration units. Any units can be used, provided that the instrument is calibrated with the appropriate standards, having concentrations of alcohol similar to the unknown breath samples.

Accordingly, a person's BAC or BrAC are now considered equivalent for the purpose of generating evidence of impairment at the wheel. Eliminating the need to convert BrAC into BAC in every single case led to a dramatic reduction in spurious litigation concerning blood/breath ratios of alcohol and inherent variability. Furthermore, the effects of alcohol on psychomotor performance, as well as roadside surveys of the risk of involvement in traffic accidents, have been conducted with breath-test instruments (e.g., the Grand Rapids survey) and not by the analysis of BAC directly. However, several U.S. states, among others New Jersey, still persist in translating the breath-alcohol readings into a presumed BAC. Indeed, the use of breath-alcohol testing was the subject of a vigorous defense challenge in 1989 in the State of New Jersey, where the Breathalyzer was well established for testing drinking drivers. The DUI statute in New Jersey stipulated that a person's blood-alcohol concentration should be estimated indirectly by analysis of the breath. The gist of the defense argument was that the 2100:1 blood/breath ratio was biased against the person being tested. Considerable expert testimony was called to answer questions about variation in the blood/breath conversion factor used. This "Downie case" was eventually settled by the Supreme Court of New Jersey ruling in favor of the continued use of the Breathalyzer 900 in law enforcement and also keeping the 2100:1 conversion factor unchanged. The bulk of the expert testimony and the most credible witnesses took the stance that breath-tests involving a 2100:1 ratio tended to underestimate the venous blood-alcohol concentration for samples taken in the post-absorptive phase of alcohol metabolism and when results are truncated to two decimal places.

When the countries in Europe introduced evidential breath-alcohol testing in the early 1980s, the threshold BrAC limits were derived from the pre-existing BAC limits on the basis of a presumed blood/breath ratio, either 2000:1, 2100:1, or 2300:1 depending on the country. Thus, 0.50 mg/mL, which is the statutory BAC limit in the Netherlands, became 220 µg/L in breath, being derived from $0.50/2300 = 0.000217$ and rounding to 0.00022, before moving the decimal point to obtain appropriate units of µg and liters. The threshold BrAC limits corresponding to already established BAC limits in different countries are shown in Table 14.1.1.

14.1.4.6 Pulmonary Function (Chronic Obstructive Pulmonary Disease)

The basic premise of breath-alcohol testing is that the concentration of alcohol in pulmonary capillary blood equilibrates with alveolar air at normal body temperature.²⁴³ However, the air in the upper airways and dead-space regions of the lungs also contains alcohol by a diffusion process from the mucous membranes receiving alcohol from blood supplying the tissue in the upper respiratory tract. Furthermore, alcohol from the upper respiratory tract may be picked up in the inspired air and deposited further down the tract during inspiration, only to be redistributed again during expiration, with some of the alveolar alcohol being deposited back into the depleted tissues of the upper airways.²⁴⁴ The net effect is that the alcohol which appears on the expired breath does so as a result of a complex dynamic process, which varies in degree from individual to individual. As indicated in the previous section, however, where the law specifies a BrAC per se offense, the actual mechanism is not relevant, and the per se BrAC offense is readily justified in terms of impairment associated with BrAC.

Modern breath-alcohol instruments are equipped with automated procedures for sampling breath and these monitor the volume exhaled and the concentration of alcohol during a prolonged exhalation. If a person manages to exhale a certain minimum volume of breath for a given length of time to satisfy the sampling requirements, a portion of the end-expired air is captured for analysis of alcohol. Some individuals, particularly those with impaired lung function, will genuinely be unable to satisfy the sampling parameters of some evidential breath-alcohol analyzers currently being used.^{245,246} Indeed, even subjects with healthy lungs, especially women of small stature and those who habitually smoke cigarettes, might have insufficient lung capacity to exhale for the minimum required time. Moreover, at high blood-alcohol concentration, the ability of a person to provide an approved sample of breath might be reduced compared with the sober state.²⁴⁷

The rules and regulations pertaining to evidential breath-alcohol testing should therefore contain an option for the suspect to provide a blood sample if he or she fails to satisfy the sampling requirements because of pulmonary limitations. In Great Britain, the policeman operating the instrument has to decide whether the suspect is not cooperating properly in providing the required sample. If this happens, the person can be charged with “failing to provide” as a separate offense that carries the same punishment as if the BrAC had been above the legal limit for driving.^{14,245} Many people charged and prosecuted for “failing to provide” in the U.K. have later been vindicated by seeking medical advice and undergoing pulmonary function tests.^{248,249} This prompted the British Home Office scientists to embark on a series of studies into the ability of people with small stature and impaired lung function to satisfy the sampling requirements of various breath-alcohol testing instruments.^{245,250} Those individuals with forced expiratory volume in one second (FEV_{1.0}) of less than 2.0 L and forced vital capacity (FVC) of less than 2.6 L were unable to use some of the breath-testing equipment evaluated. In another study with healthy subjects less than 5 ft 5 in. (165 cm) tall, some were unable to provide the required breath sample.²⁵⁰ This report, however, fails to specify the ages of the subjects, whether they were tested under the influence of alcohol, and whether they smoked cigarettes. These variables are important when the ability of a person to provide an approved breath sample has to be judged.

Asthma is an inflammatory disease of the airways causing obstruction to breathing and a reduction in air flow. Respiratory inhalers used by asthmatics contain salbutamol (β_2 -adrenergic bronchodilator) as the active ingredient. It is the mainstay treatment for acute attacks of asthma. The use of this inhaled medication just prior to being breath-tested with Intoximeter 3000 (infrared) and Alcolmeter S-D2 (electrochemistry) failed to produce a response of apparent alcohol.²⁵¹ A similar lack of response was reported for a number of nasal sprays used by people with impaired lung function.²⁵² Some asthma inhalers contain ethanol as an ingredient and this means that a response is more likely to occur immediately after their use. However, within 2 to 9 min after using a wide range of inhalers and sprays, the small positive response on the breath analyzers was eliminated.²⁵³

To test the influence of chronic obstructive pulmonary disease (COPD) on breath-alcohol analysis, patients suffering from COPD received 60 to 70 g ethanol and their blood-alcohol concentration was compared with results using the Breathalyzer model 900 at various times after drinking. The resulting blood/breath ratios were consistently higher than the 2100:1 calibration factor used with the Breathalyzer 900 instrument, so breath-tests for alcohol are not detrimental to those individuals who suffer from COPD.²⁵⁴ In a more recent study with 12 COPD patients as well as an age matched control group of subjects, alcohol (0.60 g/kg) was given by intravenous infusion and blood and breath-alcohol concentrations were determined for up to 4 h.²⁵⁵ The blood/breath ratios of alcohol in the control group and patients with COPD varied with time after infusion of alcohol and in the post-peak phase of metabolism of alcohol, the values were mostly in excess of 2400:1.²⁵⁵

Summing up these experiments in patients with pulmonary disease, there is no solid evidence to suggest that impaired lung function (asthma, COPD, emphysema) puts them at risk of being unfairly prosecuted for drunk driving when per se alcohol limits operate.^{256,257} If people with these pulmonary limitations manage to provide an approved breath sample, there is no reason to believe that the test result will be greater than for people with healthy lungs having the same blood-alcohol concentration. On the contrary, because of the higher blood/breath ratios in people suffering from COPD compared with age-matched control subjects, those with COPD who might be breath-tested have an advantage.²⁵⁵

14.1.4.7 Breathing Pattern and Hypo- and Hyperthermia

For a given individual, the concentration of alcohol expelled in the breath depends on the concentration existing in the pulmonary blood, which depends on the amount of alcohol consumed and the time after drinking when breath-tests are made.²⁴³ However, the concentration of alcohol measured in the breath at a given blood-alcohol concentration depends on numerous factors, especially the person's pattern of breathing prior to exhalation and body temperature. Also, various design features of the breath-alcohol analyzer, such as the resistance to exhalation and the geometry of the breath-inlet tube, and also the kind of mouthpiece and spit-trap fitted to the instrument, are important to consider when variations in test results have to be explained.^{258–260}

The influence of a person's breathing pattern prior to exhalation has been evaluated in several studies and variables such as breath-holding, hyper- and hypoventilation, as well as shallow breathing were investigated.²⁵⁸ Most changes in the pre-exhalation maneuver decrease the BrAC in the final exhalation compared with a control sample comprising a moderately deep inhalation and forced end-exhalation. However, breath-holding or hypoventilation before providing breath for analysis increases the concentration of alcohol in the breath-sample by about 10 to 20%.^{261,262} This higher BrAC is caused in part by a higher breath temperature and the longer time available for equilibration of alcohol with the mucous surfaces in the upper airways.²⁶³ Body temperature has an important influence on BrAC because the temperature coefficient of alcohol solubility is $\pm 6.5\%$ per degree centigrade.²⁶⁴ Local cooling of the mouth and upper-airway by breathing cold air will decrease breath-temperature and breath-alcohol concentration.²⁶⁵ Keeping ice in the mouth before and during exhalation leads to a marked lowering in the person's BrAC, in part because of the high solubility of alcohol in water condensing from the ice, and condensation of ethanol vapor in the mouth.²⁶⁶ Isothermal re-breathing devices have been described for use with breath alcohol equipment.²⁶⁷ The net effect of this device is to allow better equilibration of alcohol with all the tissues in the respiratory tract, thus raising the breath test result by about 10%, and showing a closer agreement to the blood alcohol result when a blood/breath ratio of 2100:1 is assumed.²⁶⁷

Controlled studies of the influence of hypo- and hyperthermia on breath-alcohol test results with Breathalyzer model 900 were reported by Fox and Hayward.^{268,269} The deep-core body temperature was raised by keeping volunteer subjects immersed up to their necks in water at 42°C for 45 min. This caused a 2.5°C rise in body temperature and a 23% distortion (increase) in the breath-alcohol

concentration. Immersion of the subjects up to the neck in cold water at 10°C for 45 min caused mild hypothermia and the breath-alcohol concentration decay curve was distorted downwards by 22%. When subjects were returned to normothermic conditions, the BrAC readings recovered to reach the values expected from past experience with the Breathalyzer 900, that is, results were about 10% less than the corresponding blood-alcohol concentration directly determined.

14.1.5 Concluding Remarks

The widespread use of statutory alcohol concentration limits for motorists simplifies the prosecution of drunken drivers and makes this process more effective. Accordingly, a person's blood or breath-alcohol concentration has become the single most important evidence for successfully prosecuting DUI suspects. It should, however, always be considered in the context of other evidence, such as observations about the subject's driving ability, outward behavior, and response to questions and performance in field sobriety tests. This has meant that defense arguments focus heavily on trying to discredit and cast doubt on the reliability of the result of analyzing alcohol in blood and/or breath. Of the two, it seems that results of measuring blood-alcohol are much less frequently questioned than those obtained by analyzing the breath. This probably stems from the earlier tradition of translating a measured BrAC into a presumed BAC for forensic purposes. The magnitude of variation in the conversion factor (blood/breath ratio) from person to person and in the same person over time triggered many defense challenges, which still persist today. The uncertainty in the sampling and analysis of breath and the conversion factors used have attracted much debate in the scientific literature and in the courts. The entire problem with blood/breath ratios should have been eliminated after defining the statutory alcohol limits for driving as the BrAC per se and thus sidestepping the need to convert BrAC into BAC.

Furthermore, mostly under the control of a built-in microprocessor, evidential breath-alcohol instruments are typically operated by police officers and not by chemists. This apparent vested interest in the outcome of the test result tends to make breath-alcohol testing more suspect according to some critics, and vulnerable to defense attacks compared with blood alcohol measurements performed at a forensic laboratory. Much could be done to improve forensic alcohol analysis by paying more attention to pre-analytical factors, in particular the methods and procedures used to obtain samples of body fluids (blood, breath, or urine). The responsibility for sampling, transport, and initial storage of specimens is usually in the hands of the police and other personnel who lack training in clinical laboratory methods.²⁷⁰ The use of a checklist to document certain key aspects of the sampling protocol and the various precautions taken is highly recommended.²⁷¹ Any mishaps or unusual incidents that occur during sampling, as well as the behavior and appearance of the suspect, should be carefully noted. These might become important later when the results of alcohol analysis are interpreted by the court.

The trend toward accreditation of clinical and forensic laboratories will help to standardize and document analytical procedures and establish acceptable standards of performance that minimize the risk of laboratory blunders. Forensic tests for alcohol, however, should always be held to a high standard, and where there is error, mistakes, or uncertainty, this should be honestly recognized and accrue to the defendant's favor. As long as there is a lot of money to be made in defending drunk drivers, or testifying on their behalf, there will always be lawyers and expert witnesses prepared to embark on crusades to discredit the police, the laboratory, or both. To focus an attack on the scientific background of forensic alcohol testing, a defense lawyer requires the services of an expert witness.²⁷² There are plenty of these individuals available, many of whom can be located through professional directory listings of their names, addresses, academic qualifications, experience, and often their fee. Most of these experts are willing to testify for the defense, the prosecution, or both and will generally testify in either criminal or civil litigation.

During the highly publicized *Daubert* decision from the U.S. Supreme Court, much was written about the use of scientific evidence and how best to judge the testimony of expert witnesses.²⁷³ At

about this time, an editorial in the scientific journal *Nature* made the following statement about expert witnesses:²⁷⁴

The so-called expert witness in court may be a hired-gun, willing to testify to anything for a fee, or a crackpot whose insupportable ideas are masked by an advanced degree (Ph.D.) often from a respectable university.

William S. Lovell (chemist and district attorney) made the following observation about the use and abuse of expert testimony in DUI litigation as long ago as 1972:²⁷⁵

Courts are indeed plagued by the instant expert, who whether out of a misguided eagerness to earn his fee or an overreaction to his own self-described credentials, may expound far reaching opinions.

The courtroom can be a cruel place and skillful use of expert testimony plays a much bigger role in deciding the outcome of DUI trials held in the U.S. and Britain than in continental Europe. In Britain and the U.S., the adversarial system of justice operates, which aims to establish the truth by probing the strengths and weaknesses of defense and prosecution cases.²⁷⁶ This opens the door for selecting expert witnesses known for their strong opinions and outspoken views about key elements of the scientific evidence crucial for the case. This is somewhat different from the situation in continental Europe and Scandinavia where the inquisitorial system operates and an investigating judge or judges appoint the necessary forensic experts who conduct tests and make investigations independent of the prosecution.^{277,278} This gives the impression that forensic experts evaluate the scientific evidence in a more impartial way and arrive at an opinion based on their findings. This takes the form of a written report to the court, similar to a deposition, but occasionally the expert is also expected to appear in person to present his conclusions and receive questioning from the defense and prosecution attorney.

As far as possible, expert witnesses should base their testimony on personal experience and studies they have conducted themselves and the results of which have been published in the peer-reviewed literature. But even peer-reviewers make mistakes and publication per se does not make the results gospel. Scientists are not infallible and unsubstantiated opinion is no substitute for personal experience and well designed experiments. If scientific evidence is important in criminal or civil litigation, it might be better for the judge to appoint suitably qualified experts instead of relying on witnesses chosen by the opposing sides.²⁷⁹ This was one of the recommendations of the *Daubert* decision of the U.S. Supreme Court, and has already been put into practice in Oregon, in a case concerning the health hazards of silicone breast implants.²⁸⁰ Unfortunately, the demeanor and manner of the witness often determines whether or not the evidence they present is accepted by the jury, rather than the validity of the science on which the opinion is based.²⁸¹ Complex scientific issues can usually not be satisfactorily discussed and debated in the courtroom by lawyers posing set-piece questions to expert witnesses, many of whom have poor or inappropriate qualifications and questionable motives.^{281,282} Other complicating factors are that the attorneys are often prepared to use any available means, including confusing the jury, obfuscating the issues, and impugning the expert testimony, in order to gain an acquittal, rather than pursuing an objective search for the truth.

14.2 TESTING CLAIMS OF ADVERSE DRUG EFFECTS IN THE COURTROOM

Joe G. Hollingsworth, J.D. and Eric G. Lasker, J.D.*

Spriggs & Hollingsworth, Washington, D.C.

There is something fascinating about science. One gets such wholesale returns of conjecture out of such a trifling investment of fact.

— Mark Twain, *Life on the Mississippi* (1874)

Editor's note: This section on testing claims is a new, much-needed addition to this second edition. It can be almost guaranteed that anyone who has attended a forensic conference at any time in the last 10 years has been forced to sit through a lecture on the implications of the *Daubert* decision. It can also be guaranteed with equal certainty that most of those attending the lecture neither understood nor cared a great deal about what was being said. That is unfortunate, because this is a very important ruling, and it should have an enormous effect on the way we work and testify. Readers are very fortunate to have access to this section. By illustrating the problem with a real case and real plaintiff's arguments, the authors have made the magnitude of our problem frighteningly clear.

In today's litigious society, no textbook on the potential adverse health effects of drugs would be complete without a discussion of how claims of alleged adverse drug reactions are evaluated in the courtroom. While there are many examples of licit and illicit drugs that have scientifically established adverse effects, there are also many examples of medically indicated drugs that have been pulled from the market, in whole or in part, based on perceived risks that are not borne out by the objective scientific data. Over the past 20 years, the courts have been inundated with scientifically unfounded claims that pharmaceuticals or medical devices caused adverse health effects, starting with the allegations in the 1980s that the morning sickness drug Bendectin caused birth defects and continuing in the 1990s and 2000s with claims of autoimmune disease from silicone breast implants, and claims of strokes and cardiovascular diseases from the postpartum lactation drug Parlodel. These cases have led the courts to develop important evidentiary rules that — when properly applied — prevent such unfounded claims from reaching the jury.

Ever since the U.S. Supreme Court's landmark ruling in the Bendectin case *Daubert v. Merrell Dow Pharmaceuticals, Inc.*,¹ judges have been tasked with the obligation to serve as gatekeepers to keep scientifically unreliable and irrelevant expert testimony out of the courtroom. The standards set forth in *Daubert*, which the Supreme Court has described as “exacting,”² have had a significant impact on numerous areas of legal dispute, but perhaps no area has been more affected than toxic tort and pharmaceutical product liability litigation. Under *Daubert* and its progeny, *General Electric v. Joiner*³ and *Kumho Tire Co., Ltd. v. Carmichael*,⁴ a plaintiff can no longer get a product liability claim before a jury based solely on an expert's subjective opinion that the plaintiff's injury was caused by a particular drug. Rather, the plaintiff must demonstrate that the expert's opinion is scientifically valid, both on the general causation question of whether the drug could potentially cause the injury in any patient and the specific causation question of whether the drug in fact did cause the particular plaintiff's injury.⁵

* Messrs. Hollingsworth and Lasker are partners in the Washington, D.C. law firm Spriggs & Hollingsworth, where they specialize in pharmaceutical and toxic tort litigation.

¹ 509 U.S. 579 (1993).

³ 522 U.S. 136 (1997).

⁴ 526 U.S. 137 (1999).

⁵ See, e.g., *Raynor v. Merrell Pharms. Inc.*, 104 F.3d 1371, 1376 (D.C. Cir. 1997).

Daubert has imposed a significant new obligation on trial courts, and many judges have struggled to understand the scientific principles that they must follow in their new role.⁶ Plaintiffs' counsel and like-minded legal observers have sought to take advantage of this uncertainty by arguing that the Supreme Court provided ambiguous guidance regarding the admissibility of medical causation testimony and that courts should defer to the judgment of medical experts so long as they follow the same "differential diagnosis" reasoning in their expert testimony as they do in their clinical practice.⁷ These arguments are wrong. The guidance provided by the Supreme Court is clear: expert testimony that a drug caused an adverse event is admissible only if it is based on the scientific method, i.e., evidence properly derived through the generating and testing of hypotheses. This guidance provides a simple framework for courts considering the variety of evidence generally put forth by causation experts in drug product liability litigation, whether it be epidemiology, animal research, chemical analogies, anecdotal information, or differential diagnosis.

In this chapter, we review the Supreme Court's adoption of the scientific method as the standard for admissibility of expert testimony and analyze how a court's proper understanding of the scientific method can guide it in evaluating the different types of causation evidence presented in pharmaceutical product liability litigation, both with respect to general and specific causation. Throughout this discussion and in the concluding section, we draw on our firm's experience as national defense counsel in a series of product liability cases involving the prescription drug Parlodel, in which these evidentiary issues have been analyzed in-depth in judicial opinions across the country. The Parlodel litigation has been described in another recent textbook as "the first significant products liability causation debate of the 21st century" and one that "will serve as a guide to understanding the significant causation issues that will continue to be involved, at increased rates of complexity, in the 21st century products cases."⁸

14.2.1 The Supreme Court's Directive: Expert Testimony Must Be Derived by the Scientific Method

In *Daubert*, the Supreme Court held that scientific testimony is not admissible unless it satisfies the dual requirements of scientific reliability and relevance. Scholarly debate regarding *Daubert* has often focused on the four factors suggested by the Court in determining scientific reliability: (1) testing, (2) peer review, (3) error rate and standards, and (4) general acceptance. However, a rote discussion of these factors misses the point. These factors are relevant only insofar as they assist the trial court in applying the overarching directive of *Daubert* that expert testimony must be based on the scientific method. The Supreme Court explained that "in order to qualify as 'scientific knowledge' an inference must be derived by the scientific method."⁹ The Court defined the scientific method as follows: "Scientific methodology today is based on generating hypotheses and testing them to see if they can be falsified; indeed, this methodology is what distinguishes science from other fields of human inquiry."¹⁰ Moreover, "[s]cientific validity for one purpose is

⁶ A recent survey of 400 state trial judges found that while a large majority of judges agreed that the role of "gatekeeper" was an appropriate one for a judge, most judges did not have a proper understanding of the scientific principles set forth in *Daubert*. See Sophia I. Gatowski, et al., Asking the gatekeepers: a national survey of judges on judging expert evidence in a post-*Daubert* world, 25(5) *Law and Human Behavior* 433 (2001).

⁷ See, e.g., J. Kassirer and J. Cecil, Inconsistency in evidentiary standards for medical testimony: disorder in the courts, 288(11) *JAMA* 1382-87 (Sept. 2002); M. Berger, Upsetting the balance between adverse interests: the impact of the Supreme Court's trilogy on expert testimony in toxic tort litigation, 64 *SUM Law & Contemp. Probs.* 289 (Spring/Summer 2001).

⁸ Terence F. Kiely, *Science and Litigation: Products Liability in Theory and Practice* 177 (CRC Press, Boca Raton, FL, 2002).

⁹ 509 U.S. at 590.

¹⁰ *Id.* at 593. The Supreme Court cited to two philosophical texts on the nature of scientific evidence. See *id.* (citing C. Hempel, *The Philosophy of Natural Science* 49 (1966) ("[T]he statements constituting a scientific explanation must be capable of an empirical test"); K. Popper, *Conjectures and Refutations: The Growth of Scientific Knowledge* 37 (5th ed. 1989) ("[T]he criterion of the scientific status of a theory is its falsifiability, or refutability, or testability")).

not necessarily scientific validity for other, unrelated purposes.”¹¹ In other words, expert testimony is admissible only if empirical testing validates the specific theory to which the expert opines.¹²

Daubert also explains that while admissible expert testimony must be based on the scientific method, “there are important differences between the quest for truth in a courtroom and the quest for truth in the laboratory.”¹³ “[S]cientific conclusions are subject to perpetual revision. Law on the other hand, must resolve disputes finally and quickly.”¹⁴ Accordingly, expert testimony must be judged based on the current state of scientific knowledge, not on the possibility that additional knowledge may emerge in the future. The Court recognized that the requirement of existing empirical evidence “on occasion will prevent the jury from learning of authentic insights and innovation” but held that this “is the balance struck by Rules of Evidence designed not for the exhaustive search for cosmic understanding but for particularized resolution of legal disputes.”¹⁵

Four years after *Daubert*, the Supreme Court provided further guidance on how judges should use the scientific method in evaluating expert testimony. In *Joiner*, the plaintiffs’ experts contended that their opinion (that PCBs can cause lung cancer) should be admitted because they relied on epidemiology and animal studies, which are standard tools used by scientists in testing causal hypotheses. The Court rejected this contention, explaining that a faithful application of the scientific method requires more: “whether animal studies can ever be the proper foundation for an expert’s testimony was not the issue. The issue was whether these experts’ opinions were sufficiently supported by the animal studies on which they purport to rely.”¹⁶ In other words, expert testimony must be based on empirical testing that *validates* the conclusions reached.¹⁷

The *Joiner* Court held that the research cited by plaintiffs’ experts did not validate their conclusions because the epidemiological studies did not report a statistically significant causal link between PCBs and lung cancer, lacked proper controls, and examined substances other than PCBs, and because the animal studies involved massive doses of PCBs and a different type of cancer and could not be properly extrapolated to humans. Plaintiffs’ experts could not support their opinions under the scientific method because their conclusions ultimately rested on subjective leaps from the scientific evidence. “[N]othing in either *Daubert* or the Federal Rules of Evidence requires a district court to admit evidence that is connected to existing data only by the *ipse dixit* of the expert. A court may conclude that there is simply too great an analytical gap between the data and opinion proffered.”¹⁸

Two years later, in *Kumho Tire*, the Supreme Court held that the *Daubert* requirements of reliability and relevance apply to all expert testimony, including experience-based testimony. Even in areas where the four factors proposed in *Daubert* are inapplicable, the Court explained that the overarching question remains the same: Is the expert’s testimony supported by a methodology that has been objectively validated and supports the conclusions offered?¹⁹ In evaluating this question,

¹¹ *Id.* at 591.

¹² The four factors discussed in *Daubert* provide different methods by which an expert’s opinion can be analyzed for adherence to the scientific method. Two of the factors, testing and error rates, are integral parts of the scientific method itself. The other two factors, peer review and general acceptance, can provide independent support that the opinion was properly derived by the scientific method. Peer review, however, should not be mindlessly equated with publication. As the Supreme Court noted, publication “is but one element of peer review.” *Daubert*, 509 U.S. at 593. Peer review, like general acceptance, refers more broadly to the concept that the theory at issue has been subjected to and found valid through empirical testing by the broader scientific community. See generally W. Anderson, et al., *Daubert’s* backwash: litigation-generated science, 34 *U. Mich. J.L. Reform* 619 (2001); E. Chan, The “Brave New World” of *Daubert*: true peer review, editorial peer review, and scientific validity, 70 *N.Y.U. L. Rev.* 100 (1995).

¹⁶ 522 U.S. at 145.

¹⁷ See *id.* at 146 (“conclusions and methodology are not entirely distinct from one another”).

¹⁸ *Id.*

¹⁹ See 526 U.S. at 157 (noting with respect to challenged tire expert’s testimony that “despite the prevalence of tire testing,” plaintiffs did not “refer to any articles or papers that validate [the expert’s] approach”).

the Court instructed that courts should consider whether the expert “employs in the courtroom the same level of intellectual rigor that characterizes the practice of the expert in the relevant field.”²⁰

14.2.2 Evaluating General Causation Evidence under the Scientific Method

General causation opinions in drug product liability litigation may be based on a wide variety of evidence of differing scientific value, including, *inter alia*, epidemiology, animal studies, chemical analogies, case reports, and regulatory findings and other secondary sources. Some legal observers have argued that a medical expert’s evaluation of this evidence involves a “complex inferential process” and that the expert accordingly should be allowed to simply lump this evidence together and reach “a subjective judgment about the strength of the evidence.”²¹ However, *Daubert* clearly requires more. Under *Daubert*, a trial court must consider each of these categories of evidence in light of the scientific method, and the expert’s testimony may only be admitted if the expert can establish through scientific evidence that her causal hypothesis has been reliably tested and validated.

Further, causation experts cannot satisfy their *Daubert* burden by arguing that the scientific research necessary to test their hypothesis has not been or cannot be performed. *Daubert* requires trial judges to evaluate expert testimony based on the science that exists at the time, not the possibility of new scientific discoveries in the future or guesswork as to what those discoveries might show.²² As Judge Posner of the U.S. Court of Appeal for the Seventh Circuit explained, “the courtroom is not the place for scientific guesswork, even of the inspired sort. Law lags science, it does not lead it.”²³

14.2.2.1 Epidemiology

Controlled epidemiological studies are generally considered the most reliable evidence for testing a hypothesis that a particular substance causes a particular injury in humans.²⁴ Epidemiological studies can be especially important in cases where the drug or substance at issue is widely used or where there is a measurable background rate of the alleged injury regardless of exposure. In these situations, epidemiology may be the only way to test the hypothesis that observed injuries in exposed individuals are reflective of an increased risk and a causal connection rather than pure statistical chance.²⁵ While the absence of epidemiology may not be fatal to a plaintiff’s case,

²² 509 U.S. at 597.

²³ *Rosen v. Ciba-Geigy Corp.*, 78 F.3d 316, 319 (7th Cir. 1996).

²⁴ *See, e.g., Soldo v. Sandoz Pharms. Corp.*, 244 F. Supp. 2d 434, 532 (W.D. Pa. 2003) (epidemiology is “the primary generally accepted methodology for demonstrating a causal relation between a chemical compound and a set of symptoms or a disease”) (quoting *Conde v. Velsicol Chem. Corp.*, 804 F. Supp. 972, 1025–26 (S.D. Ohio 1992), *aff’d*, 24 F.3d 809 (6th Cir. 1994)); *Hollander v. Sandoz Pharms. Corp.*, 95 F. Supp. 2d 1230, 1235, n.14 (W.D. Okla. 2000) (“In the absence of an understanding of the biological and pathological mechanisms by which disease develops, epidemiological evidence is the most valid type of scientific evidence of toxic causation”), *aff’d*, 289 F.3d 1193 (10th Cir. 2002); *Breast Implant Litig.*, 11 F. Supp. 2d 1217, 1224–25 (D. Colo. 1998) (same, citing cases).

²⁵ There has been recent controversy regarding whether certain types of epidemiological studies should be considered inherently more reliable than others in establishing causation. Historically, courts have understood that randomized controlled clinical trials are less likely to report erroneous associations than observational epidemiological studies, like cohort or case control studies. *See In re Rezulin Prod. Liab. Litig.*, 369 F. Supp. 2d 398, 406 (S.D.N.Y. 2005); *see also* David H. Kaye and David A. Freeman, *Reference Guide on Statistics*, Reference Manual on Scientific Evidence (2d ed. 2000) at 94–95. However, recent research suggests that this understanding may be mistaken, *see* John Concato, et al., Randomized, controlled trials, observational studies, and the hierarchy of research design, 342(25) *N. Engl. J. Med.* 1887 (2000); John Concato, Observational versus experimental studies: what’s the evidence for a hierarchy? 1 *J. Am. Soc. Exp. NeuroTherapeutics* 341 (2004). In a recent review of the most highly cited clinical research (defined as studies cited more than 1000 times in the literature), a scientist concluded that 16% of the top-cited clinical research studies relating to medical interventions had been contradicted within the following 15 years and another 16% were followed by subsequent research suggesting that the initial findings may have been overstated. John P.A. Ioannidis, Contradicted and initially stronger effects in highly cited clinical research, 294(2) *JAMA* 218 (2005). While epidemiological evidence can provide the best evidence of causation, as explained below, even the best study cannot establish that causation in fact exists.

numerous courts have held that a plaintiff seeking to establish causation without such evidence will face a high evidentiary hurdle.²⁶

When causation experts rely on epidemiological studies to support their opinions, a trial court must analyze those studies to determine whether they provide a proper foundation for the expert's testimony under the scientific method. The finding in an epidemiological study of an *association* between a substance and an injury is not equivalent to *causation*.²⁷ There are three reasons that a positive association may be observed in an epidemiological study: (1) chance, (2) bias, and (3) real effect.²⁸ As the Supreme Court recognized in *Joiner*, epidemiological research cannot provide a scientifically reliable basis for an affirmative causation opinion if it is statistically insignificant or inadequately controlled for bias.²⁹

Epidemiologists attempt to account for the possibility of chance by calculating "confidence intervals" around point estimates of potential increased risk derived from epidemiological studies. An epidemiological study is considered to show a statistically significant association with an increased risk if the confidence interval of upper- and lower-bound estimates of risk does not include the possibility of no increased risk in the exposed population. The possibility of no increased risk is referred to as the "null" hypothesis, which is generally indicated by a relative risk or odds ratio of 1.0.³⁰ The generally accepted confidence interval in epidemiological studies is 95%, meaning that a study is not statistically significant unless the "null" hypothesis of no increased (or decreased) risk can be excluded with 95% confidence.³¹ If an epidemiological study is not statistically significant, it cannot provide scientifically reliable evidence of an association, let alone causation.³² Further, numerous courts have held that epidemiological evidence can only support a conclusion that a substance is more likely than not the cause of disease if it establishes a doubling of the risk of the disease.³³ The reasoning behind this requirement is that if exposure does not at least double the risk of injury, then more than half of the exposed population suffering from injuries allegedly caused by the substance would have been injured anyway through pure chance (based on the background risk of injury) thereby disproving "more likely than not" legal causation. Courts have also cautioned against reliance on statistically significant subgroup analyses, given the likelihood that numerous subgroup analyses will result in spurious statistical associations in some end points through chance alone.³⁴

Bias in epidemiology is any systematic error that makes the two groups being compared different in more ways than just the variable being studied.³⁵ Common sources of bias include confounding factors (other factors associated with the studied factor that might account for a perceived increased risk), selection bias (uncontrolled differences between the studied populations), and information

bias (systematic error in measuring data that results in differential accuracy of information).³⁶ A court must consider each of these sources of bias in interpreting an epidemiological study because bias can produce an erroneous association.³⁷ Thus, for example, courts have excluded expert causation testimony based on purported statistically significant epidemiologic evidence where the study failed to account for other confounding exposures that could have accounted for the apparent association.³⁸ Courts have rejected expert opinions that relied on epidemiological studies where the subjects were not blinded to the study hypothesis.³⁹ Courts have rejected expert testimony based on epidemiological studies that failed to adequately address the possibility that injured subjects would be more likely to recall a preceding exposure than healthy controls (“recall bias”).⁴⁰ Courts have also rejected expert testimony that relied upon epidemiological studies that failed to articulate selection criteria for participants in the study and thus could not account for selection biases “that could lead to erroneous inferences regarding causation.”⁴¹

The existence of a well-controlled epidemiological study that reports a statistically significant increased association with a specific injury does not, by itself, provide scientifically reliable evidence establishing causation.⁴² “The strong consensus among epidemiologists is that conclusions about causation should not be drawn, if at all, until a number of criteria have been considered.”⁴³ In analyzing the scientific reliability of epidemiological evidence under *Daubert*, a number of courts have been guided by a set of criteria published by the noted epidemiologist, Sir Austin Bradford Hill in 1965 (“the Bradford Hill criteria”).⁴⁴ The Bradford Hill criteria can be summarized as follows: (1) strength of association, (2) consistency and replication of findings, (3) specificity with respect to both the substance and injury at issue; (4) evidence of a dose-response relationship, (5) temporal relationship, (6) biological plausibility, and (7) consideration of alternative explanations.⁴⁵

In light of these criteria, courts have rejected statistically significant epidemiological research under *Daubert* where the reported relative risk is only slightly elevated⁴⁶ and have suggested that epidemiological research reporting a relative increased risk of less than three times indicates only a weak association (strength of association).⁴⁷ Courts have also rejected isolated, statistically

Supp. 2d at 1227 (same).

⁴⁷ See *Havner*, 953 S.W.2d at 719.

significant epidemiological findings that are not replicated in other epidemiological research (consistency).⁴⁸ Courts have rejected epidemiological studies reporting statistically significant associations with allegedly similar substances or allegedly similar injuries (specificity).⁴⁹ And courts have rejected alleged associations in epidemiological studies that did not demonstrate a dose–response relationship (dose response).⁵⁰ Moreover, courts have not accepted the mere incantation of the name of Bradford Hill as establishing the reliability of a causation hypothesis.⁵¹ These criteria must be applied faithfully or they can also generate unreliable conclusions,⁵² as demonstrated by two review papers published in 1989–1990 that both purported to use the Bradford Hill criteria to assess the epidemiological evidence regarding an association between alcohol consumption and breast cancer, but reached dramatically different conclusions.⁵³

Causation experts sometimes attempt to bolster individually weak epidemiological studies by relying on “meta-analyses” in which otherwise insignificant or inconsistent findings are pooled to generate a single purportedly significant finding. This approach was rejected by courts in the Bendectin litigation,⁵⁴ and rightfully so. While meta-analyses can provide useful information if conducted pursuant to proper scientific methodology, they have frequently reported causal relationships that do not survive scientific scrutiny.⁵⁵ By pooling data from different studies, meta-analyses can paper over biases and other weaknesses in the underlying studies, disregard inconsistent findings, and improperly combine divergent population groups. As one commentator has explained, “[m]eta-analyses begin with scientific studies, usually performed by academics or government agencies, and sometimes incomplete or disputed. The data from these studies are then run through computer models of bewildering complexity, which produces results of implausible precision.”⁵⁶ After finding that meta-analyses were frequently contradicted by subsequent large, randomized controlled trials, another investigator cautioned: “The popularity of meta-analysis may at least partly come from the fact that it makes life simpler and easier for reviewers as well as readers. However, simplification may lead to inappropriate conclusions.”⁵⁷ Pursuant to *Daubert*, a court

⁴⁸ See, e.g., *Miller v. Pfizer, Inc.*, 196 F. Supp. 2d 1062, (D. Kan. 2002) (expert failed to address “fact that other research is contrary to his conclusion”), *aff’d*, 356 F.3d 1326 (10th Cir.), *cert denied*, 125 S. Ct. 40 (2004); *Havner*, 953 S.W.2d at 727 (“if scientific methodology is followed, a single study would not be viewed as indicating that it is ‘more probable than not’ that an association exists”).

⁴⁹ See *Joiner*, 522 U.S. at 145–46 (studies proffered as evidence of PCB-lung cancer link involved exposures to mineral oils or other potential carcinogens); *Burleson v. Tex. Dep’t. of Criminal Justice*, 393 F.3d 577, 585–86 (5th Cir. 2004) (rejecting expert testimony where expert could not point to epidemiological studies demonstrating statistically significant link between thorium dioxide exposure and plaintiff’s type of lung or throat cancer); *Allison*, 184 F.3d at 1315 (studies reported link to injuries not suffered by plaintiff); *Schudel v. Gen. Elec. Co.*, 120 F.3d 991, 997 (9th Cir. 1997) (studies involved exposures to organic solvents other than those at issue); *Magistrini*, 180 F. Supp. 2d at 603–04 (to same effect).

must look behind the “bewildering complexity” of meta-analysis and protect against “inappropriate conclusions” by requiring the expert to establish the reliability and relevance both of the different pieces of information going into the meta-analysis and the calculations used to combine the information into a single result.

14.2.2.2 *Animal Research*

Animal research may be a useful tool for raising suspicions that can then be tested in humans, but there are significant differences in humans and laboratory animals that limit the degree to which animal research can validate a causation hypothesis in humans.⁵⁸ There are numerous examples of apparent positive findings in animal studies that have subsequently been found inapplicable to humans. The most commonly cited example, perhaps, is saccharine, which was linked to bladder cancer in rats over 20 years ago but was recently removed from the National Toxicology Program list of potential human carcinogens after years of subsequent research failed to find any health risk in humans. Similarly, scientists have determined that a common insecticide, carbaryl, causes fetal abnormalities in dogs because dogs lack a specific enzyme involved in metabolizing carbaryl. Humans have the enzyme at issue and are accordingly not believed to be at risk.⁵⁹ Because of numerous such problems of extrapolation, courts repeatedly have held that animal studies alone cannot prove causation in humans.⁶⁰

At a minimum, extrapolations from animal studies to humans are not considered reliable in the absence of a credible scientific explanation why such extrapolation is warranted.⁶¹ In evaluating whether animal studies can form a reliable foundation for a causation opinion, trial courts should consider such factors as (1) whether the results followed a dose–response curve; (2) whether the animal studies involved massive doses, (3) whether the studies involved different routes of administration, (4) whether the studies are conducted in intact animals (as opposed, e.g., to isolated animal parts), (5) whether the results have been replicated in different animal species, and (6) whether the animal models have been shown to be reliable predictors of human experience.⁶²

Animal toxicology studies are not designed to establish whether a substance is safe in humans but rather to allow scientists to study the types of effects a substance can produce under specified conditions.⁶³ Accordingly, animal studies are often conducted with the goal of inducing the greatest number of adverse effects. This is accomplished in a number of ways, including the use of extremely high doses and exposures through special routes designed to deliver the substance directly to a particular organ without allowing for normal absorption and metabolism.⁶⁴ While these models are useful and appropriate in the laboratory as a means to generate hypotheses for further testing, they create additional problems for extrapolating study findings to humans.

⁵⁸ See, e.g., Irva Hertz-Picciotto, Epidemiology and quantitative risk assessment: a bridge from science to policy, 85(4) *Am. J. Public Health*. 484, 485 (1995) (“The uncertainty stemming from interspecies extrapolation is far larger than the uncertainty resulting from uncontrolled bias or errors in exposure information in epidemiological studies”).

⁵⁹ See Bernard D. Goldstein and Mary Sue Henifen, *Reference Guide on Toxicology*, Reference Manual on Scientific Evidence 420 n.48 (2d ed. 2000). ⁶² See, e.g., *Joiner*, 522 U.S. at 144; *Hollander*, 289 F.3d at 1209; *Turpin*, 959 F.2d at 1358–61; *In re Rezulin Prod. Liab. Litig.*, 369 F. Supp. 2d at 406–07; *Caraker*, 188 F. Supp. 2d at 1037; *Wade-Greaux*, 874 F. Supp. at 1477.

⁶³ See Eaton and Klaassen, at 27, *supra* note 59.

⁶⁴ See Eaton and Klaassen, at 27, *supra* note 59; Karl K. Rozman and Curtis D. Klaassen, Absorption, distribution, and excretion of toxicants, in *Casarett & Doull’s Toxicology: The Basic Science of Poisons*, at 111.

The existence of a dose–response relationship has been described as the most fundamental and pervasive concept in toxicology.⁶⁵ All substances, even water, become toxic at a high enough dose. Conversely, however, “it has long been recognized that acute toxicological responses are associated with thresholds; that is, there is some dose below which the probability of an individual responding is zero.”⁶⁶ As stated by the oft-described father of chemical pharmacology, Paracelsus (1493–1541), “What is there that is not poison? All things are poison and nothing [is] without poison. Solely a dose determines that a thing is not a poison.”⁶⁷ Accordingly, even leaving to one side the issue of inter-species variations, the fact that a high-dose study results in adverse effects in animals cannot be extrapolated into a scientifically reliable conclusion that the substance can cause such effects at normal exposure levels in humans.⁶⁸ To the contrary, because toxic effects in humans are generally expected to appear in the same range on the basis of dose per unit of body surface as in experimental animals, a finding of adverse events in animals at only very high doses may be more indicative of the safety of the substance in normal use.⁶⁹

The route by which a substance enters the body can also have a significant effect on its toxicity. Animal researchers frequently administer chemical agents through special routes, including, *inter alia*, (1) intraperitoneal, (2) subcutaneous, (3) intramuscular, and (4) intravenous.⁷⁰ These routes of administration may bypass the normal mechanisms through which potential toxins are removed before reaching the general circulation. For example, many substances are biotransformed and detoxified by the liver; while these substances may demonstrate toxic effects when injected intravenously, intramuscularly, or subcutaneously, they are perfectly safe if ingested orally.⁷¹ Likewise, animal researchers also use genetically designed or physically altered animals in which normal protective body mechanisms are removed.⁷² These types of animal studies can be useful in studying how an animal’s normal body mechanisms interact and how substances can affect isolated physiological systems, but they do not reflect real-world risks, even in the species being studied.

In conducting its *Daubert* inquiry, a trial court also must determine whether the findings in the animal studies “fit” the opinions being offered in the case. Thus, an expert cannot rely on animal research that relates to a different injury than the one at issue. For example, animal carcinogenicity studies indicate that animals “react differently and in much more diverse ways than man” and that “compared to humans much more variation occurs in the cancer sites in animals.”⁷³ However, in cases in which a chemical has been associated with cancers in both animal studies and epidemiological studies, “the target organ is usually identical.”⁷⁴ In *Joiner*, the Supreme Court thus rejected animal research in part because the animals had developed a different type of cancer than the cancer at issue in the plaintiff.⁷⁵

⁶⁵ See Eaton and Klaassen, at 17–18, *supra* note 59.

⁶⁶ *Id.*, at 21.

⁶⁷ *Id.*, at 13.

⁶⁸ See, e.g., Meijers, *supra* note 59, at 100 (concluding based on a comparison of animal and epidemiological studies for specific chemicals that “chemicals with little or no cancer potential in humans have been tested at too high concentrations in rodents... which resulted in the observed carcinogenic effect”).

⁶⁹ *Id.*, at 27. Federal regulatory agencies such as the Environmental Protection Agency thus use high-dose animal research as a basis for establishing conservative regulatory safe exposure levels for humans (albeit at levels several multiples below that found to have no effect in animals). See, e.g., Faustman and Omenn, *supra* note 59, at 92–94.

14.2.2.3 Chemical Analogies

Causation opinions derived from chemical analogies rely on the hypothesis that a substance's effects can be predicted based on the established effects of similarly structured compounds. Trial courts should be very wary of such "guilt-by-association" evidence,⁷⁶ particularly where there is scientific research involving the actual substance at issue that demonstrates differences between it and its purported chemical cousins. Because even small changes in molecular structure can radically change a particular substance's properties and propensities, research in analogous substances does not reliably test the causal hypothesis at issue.⁷⁷

The difficulty in relying on chemical analogies has been demonstrated by attempts to create computerized programs to assess the toxicity of chemical agents based on structure–activity relationships (SARs). These computerized models are far more sophisticated than the simplistic chemical analogies often relied on by causation experts in toxic tort litigation, and often rely on additional information regarding a substance beyond its chemical structure. Even so, while these models ultimately may prove helpful in setting research priorities or generating hypotheses, they have failed to provide reliable predictions as to a chemical's toxic effect.⁷⁸ As reported in a recent survey article, two prediction toxicity exercises conducted in recent years under the aegis of the National Toxicology Program have found that models that attempt to predict carcinogenicity "based solely on information derived from chemical structure" have been particularly unreliable, with the first exercise reporting that "overall accuracy in terms of positive or negative predictions was in the range 50–65%" and the ongoing second exercise reporting even higher error rates in preliminary results.⁷⁹ Moreover, "[a] clear limitation of almost all the prediction systems ... was their excessive sensitivity, i.e., incorrectly predicting many non-carcinogens as positive."⁸⁰ Efforts to predict toxicity based on structure activity relationships have resulted in similar problems.⁸¹

14.2.2.4 Case Reports/Case Series

Case reports and case series are anecdotal observations of adverse effects occurring in coincidence with exposure to a given substance. If a sufficient body of similar case reports appear in the literature, they can spur epidemiological or other controlled research to test the hypothesis that a causal link exists.⁸² However, as most courts have properly recognized, case reports themselves do

⁷⁶ *Caraker*, 188 F. Supp. 2d at 1038; *see also Soldo*, 244 F. Supp. 2d at 549 ("Other federal courts facing proffered expert testimony based on the effects of allegedly similar compounds have reached the same conclusion and rejected such contentions: these courts have found that consideration of the effects of *other* drugs can only lead away from the truth.") (citing cases).

⁸⁰ Richard and Benigni, *supra* note 78, at 8; *see also* Ashby and Tenant, *supra* note 78, at abstract ("carcinogenicity tends to be overpredicted by this integrated technique" of basing predictions on chemical structure, genotoxicity and rodent toxicity).

⁸¹ *See* James D. McKinney, et al., Forum: the practice of structure activity relationships (SAR) in toxicology, 56 *Toxicol. Sci.* 8, 15 (2000) ("Given the huge range and variability of possible interactions of chemicals in biological systems, it is highly unlikely that SAR models will ever achieve absolute certainty in predicting a toxicity outcome, particularly in a whole-animal system.").

⁸² *See* Howard Hu and Frank E. Speizer, Influence of environmental and occupational hazards on disease, in *Harrison's Principles of Internal Medicine* 19 (Braunwald, et al. eds. 15th ed. 2001) ("Case reports either sent to local authorities or published in the literature often prompt follow-up studies that can lead to the identification of new hazards"); David A. Grimes and Kenneth F. Schulz, Descriptive studies: what they can and cannot do, 359 *Lancet* 145 (Jan. 12, 2002) ("epidemiologists and clinicians generally use descriptive reports to search for clues of cause of disease — i.e., generation of hypotheses"); J.A. Arnaiz, et al., The use of evidence in pharmacovigilance: case reports as the reference source for drug withdrawals, 57 *Eur. J. Clin. Pharmacol.* 89–91 (2001).

not test the causal hypothesis and accordingly cannot support a causation opinion under *Daubert*.⁸³ Case reports are merely anecdotal accounts of observations in particular individuals; they are not controlled tests, frequently lack analyses, and frequently make little attempt to screen out alternative causes for a patient's condition.⁸⁴ As discussed above, when the substance at issue is widely used, it is statistically certain given general background rates of injury that there will be case reports in which an exposure and an injury coincidentally coincide. Accordingly, the existence of such case reports is of little scientific value.⁸⁵

In drug product liability cases, causation experts may rely on so-called "causality assessments" of individual case reports. Causality assessments are algorithms used in some European pharmacovigilance regulatory schemes that seek to impose some structure on evaluation of individual case reports by creating standardized questions to be used in the review of such reports, such as:

- Was the adverse event a known consequence of the drug?
- Did the event occur in temporal proximity to the use of the drug?
- Did the symptoms disappear upon withdrawal of the drug ("dechallenge")?
- Did the symptoms reappear following reintroduction of the drug (rechallenge)?
- Are there alternative causes for the adverse event?

Reviewers then grade individual case reports using such terms as "not possible," "unlikely," "possible," and "probable."⁸⁶ Causality assessments are used by some regulatory agencies as a signaling tool, but "they have no objective reliability which would render them useful in a wider environment."⁸⁷ "None of the available causality assessment systems has been validated.... In other words the uncertainty [inherent in case reports] is not reduced, but categorized (at best in a semiquantitative way)."⁸⁸ Studies of standardized causality assessments have repeatedly found significant disagreements between graders using the same assessment methodology.⁸⁹ Accordingly, causality assessments carry no greater scientific weight than other case reports and likewise cannot provide the type of evidence required under *Daubert*.⁹⁰

Some case reports include information regarding purported dechallenges or rechallenges, *i.e.*, reports that a patient's condition improved when the substance was removed or worsened when the substance was reintroduced. Where the dechallenge/rechallenge report is merely an after-the-fact account of an anecdotal observation, it suffers from similar reliability problems as other case reports. Many medical conditions result in fluctuations in symptomology in the ordinary course, and apparent temporal associations with exposure may be due to pure chance. Even if the dechallenge or rechallenge is conducted prospectively with the intent of testing a causal hypothesis, a

⁹⁰ See *Glastetter v. Novartis Pharms. Corp.*, 107 F. Supp. 2d 1015, 1037 n. 21 (E.D. Mo. 2000) ("like case reports ... a causality assessment involves only one individual, and, in any event, is not sufficient to establish causation") *aff'd*, 252 F.3d 986 (8th Cir. 2001); *Soldo*, 244 F. Supp. 2d at 545 (plaintiff has failed to show that the causality assessment "methodology — adopted for foreign regulatory purposes — meets any of the *Daubert* criteria, nor has plaintiff shown any other indicia of reliability.").

perceived effect in one person has limited scientific value at best.⁹¹ Because the data are limited to a single observation, a trial court must be particularly diligent in determining whether the dechallenge/rechallenge was conducted under strict controls to account for potential confounding influences. Prospective dechallenge/rechallenge experiments — sometimes referred to as “single subject” or “n of 1” experiments — have numerous limitations that preclude general causation conclusions.⁹² “[W]ithout strong assumptions regarding how an intervention on one individual relates to its effects on others, the results from a single-subject design provide little useful information ... [and e]xamination of a single subject cannot verify those assumptions.”⁹³ As courts have explained, a prospective dechallenge/rechallenge report “constitutes but one single, uncontrolled experiment.”⁹⁴

14.2.2.5 Secondary Source Materials

In addition to actual scientific or anecdotal data, causation experts will sometimes rely on secondary source materials that cite to the primary evidence, such as regulatory materials, textbooks, and internal company documents. These secondary materials do not add any additional scientific knowledge and are no more reliable than the evidence they cite.⁹⁵ They do not test a causal hypothesis; they merely report the findings of others.

In particular, regulatory findings do not provide relevant “peer review” for a causation opinion, because they are based on a risk–utility analysis that involves a much lower standard of proof than that which is demanded by a court of law.⁹⁶ For example, a recent article reported that the vast majority of regulatory withdrawals of approvals for drugs in Spain during the 1990s were based solely on case reports.⁹⁷ As one commentary observed, “law, societal considerations, costs, politics, and the likelihood of litigation challenging a given regulation all influence the level of scientific proof required by the regulator decision-maker in setting regulatory standards and make such standards problematic as reference points in litigation.”⁹⁸

14.2.3 Causation Opinions Based on Clinical Reasoning

The question whether clinical reasoning can reliably support a causation opinion must be considered separately with respect to general causation and specific causation. Doctors do not in their ordinary clinical practice reach scientifically reliable determinations regarding general causation; they make individualized treatment decisions based on the exigencies of the moment. Accordingly, clinical reasoning cannot reliably support a general causation opinion. On the other hand, clinical reasoning through a differential diagnosis may provide reliable support for a specific causation opinion, so long as the diagnosis is reached in a manner that it is faithful to the scientific

Rodricks and Susan H. Rieth, Toxicological risk assessment in the courtroom: are available methodologies suitable for evaluating toxic tort and product liability claims?, 27 *Regul. Toxicol. Pharmacol.* 21, 27 (“The public health-oriented resolution of scientific uncertainty [used by regulators] is not especially helpful to the problem faced by a court.”).

⁹⁷ See Arnaiz, *supra* note 82.

⁹⁸ Rodricks and Rieth, *supra* note 96, at 30.

method. Differential diagnoses conducted for tort litigation purposes raise unique issues of reliability, however, because they generally are conducted *post hoc* and not in the context of medical treatment.

14.2.3.1 Clinical Reasoning and General Causation

Doctors in their day-to-day practice are required to make treatment decisions for individual patients based on the clinical information before them. These clinical judgments do not provide a reliable basis for a general causation opinion.⁹⁹ Doctors do not conduct scientific testing in their daily practice to determine whether particular substances can cause particular injuries. Indeed, few doctors have more than a rudimentary training in the scientific methods used to determine causation.¹⁰⁰ Instead, they reach working diagnoses and make conservative medical judgments based on their Hippocratic oath to “first, do no harm.”¹⁰¹ Thus, for example, if a patient reports a recent exposure to a new medication or chemical substance, the doctor may order the patient to avoid further exposures based not on a scientific determination of causality but simply as a no-risk prophylactic measure.¹⁰²

While doctors may reach tentative opinions regarding causation in the course of providing treatment, their opinions are not reached pursuant to the scientific method, but are instead based on inferential leaps that allow them to provide immediate therapeutic care. Clinical causation opinions based on differential diagnosis are “a mixture of science and art, far too complicated for its accuracy to be assessed quantitatively or for a meaningful error rate to be calculated.”¹⁰³ Moreover, differential diagnosis only “follow[s] the causal stream up to a point where intervention is possible” because, typically, physicians “do not care about a disease’s etiology ... unless understanding causation would assist in diagnosis and treatment.”¹⁰⁴ As one court recently explained,

Doctors in their day-to-day practices stumble upon coincidental occurrences and random events and often follow human nature, which is to confuse association and causation. They are programmed by human nature and the rigors and necessities of clinical practices to conclude that temporal association equals causation, or at least that it provides an adequate proxy in the chaotic and sometimes inconclusive world of medicine. This shortcut aids doctors in their clinical practices because the most important objective day-to-day is to help their patients and “first do no harm,” as their Hippocratic oath requires. Consequently, they make leaps of faith.... [This type of] clinical impression is not the sort of scientific methodology that *Daubert* demands.¹⁰⁵

Plaintiffs’ counsel seeking to rely on clinical reasoning to support a general causation opinion will often cite to the language in *Kumho Tire* that an expert must “employ in the courtroom the same level of intellectual rigor that characterizes the practice of the expert in the relevant field.”¹⁰⁶ This argument is misplaced, because, as explained above, “the relevant field[s]” for a general causation opinion are epidemiology and toxicology, not clinical medicine.¹⁰⁷ Plaintiffs’ counsel will also argue that differential diagnosis is a well-recognized, scientifically reliable technique. But differential

⁹⁹ See *Soldo*, 244 F. Supp. 2d at 508; *Siharath*, 131 F. Supp. 2d at 1362; *In re Breast Implant Litig.*, 11 F. Supp. 2d at 1230; *Hall*, 947 F. Supp. at 1413.

¹⁰⁷ See *Siharath*, 131 F. Supp. 2d at 1362; Michael B. Kent, Jr., *Daubert*, doctors and differential diagnosis: treating medical causation testimony as evidence, 66 *Def. Couns. J.* 525, 532–33 (1999).

diagnosis is a reliable methodology only for “ruling out” alternative causes of injury from a list of possible causes; it does not “rule in” a substance as a potential cause in the first instance.¹⁰⁸

14.2.3.2 Clinical Reasoning and Specific Causation

Although insufficient for purposes of general causation, a differential diagnosis may provide a scientifically reliable basis for a specific causation opinion — *i.e.*, that an established toxin in fact caused a plaintiff’s injury. However, an expert’s bare assertion that the expert applied a differential diagnosis is not sufficient to satisfy *Daubert*. A trial court must determine whether the differential diagnosis is based on a reliable methodology. Accordingly, the expert must demonstrate that the differential diagnosis was based on a sufficient and valid clinical investigation.¹⁰⁹ The expert also must have a scientifically reliable basis for excluding alternative causes of the plaintiff’s injury, including the possibility that the injury was idiopathic.¹¹⁰

In analyzing the reliability of a specific causation opinion based on differential diagnosis, trial courts must ensure that the expert employs “the same level of intellectual rigor” in the courtroom as a treating physician would employ in the ordinary care of patients.¹¹¹ An expert cannot simply look for all possible causes of a person’s illness from the universe of potential causes and declare that each of them — including the exposure at issue — should be considered actual but for causes for purposes of tort liability.¹¹² Even if an expert can show reliable scientific evidence supporting some level of increased risk from a drug, the expert cannot reliably point to the drug as the cause of an individual plaintiff’s injury if that plaintiff has other independent risk factors that are more strongly associated with the injury in question. For example, assume that there is scientifically reliable epidemiological evidence showing a three times statistically significant increased risk of stroke in patients who used a given drug X. That evidence may be sufficient to support an expert’s specific causation opinion with regard to a plaintiff who has no other risk factor for stroke. However, it would not be sufficient to support a specific causation opinion with regard to a patient who also suffers from uncontrolled hypertension and has smoked a pack of cigarettes a day for the past 20 years, given the greater risks posed by those comorbid conditions. Where a plaintiff has other established risk factors that could have caused the plaintiff’s injury, the expert must explain how he ruled out these other potential causes to reliably support an opinion that the injury was due instead to a drug exposure.¹¹³

A trial court also needs to evaluate an expert’s differential diagnosis in light of the artificial circumstances in which it is reached. Unlike differential diagnoses conducted by doctors in their day-to-day practice, a differential diagnosis in a litigation context is often conducted in support of an already asserted legal claim of causation. This raises myriad possibilities of bias, both intentional and unintentional.

Consider a hypothetical example of typical large-scale drug product liability litigation. Based on anecdotal reports of adverse events and possibly pressure from special interest organizations like Public Citizen, the FDA recommends labeling changes or withdraws approval of a drug.¹¹⁴ The same day, if not before, plaintiffs’ firms will begin advertising for potential plaintiffs through

¹¹² See *Cano v. Everest Minerals Corp.*, 362 F. Supp. 2d 814, 846 (W.D. Tex. 2005).

¹¹³ See *Wills v. Amerada Hess Corp.*, 379 F.3d 32, 50 (2d Cir. 2004) (excluding expert’s specific causation opinion that plaintiff’s squamous cell carcinoma had been caused by polycyclic aromatic hydrocarbons where plaintiff was a smoker and heavy consumer of alcohol); *Easter v. Aventis Pasteur, Inc.*, 358 F. Supp. 2d 574, 577 (E.D. Tex. 2005) (expert could not reliably point to thimerosal in vaccine as a cause of plaintiff’s neurological injuries where plaintiff had autism that could not be linked to vaccine and was independently associated with such injuries).

¹¹⁴ As discussed *supra* at 1160, such regulatory action is not the equivalent of a finding of causation.

various forms of media, including the Internet, television, radio, and print media. Provided that the drug has been used by a relatively large number of patients, there will be a ready population of patients who had adverse events while taking the drug based solely on statistical chance due to the background rates of such events regardless of drug use. Accordingly, plaintiffs' counsel can quickly gather a large pool of potential plaintiffs.

Plaintiffs' counsel will then start weeding through that pool to exclude individuals with obvious alternative causes for their injuries and patients whose injury did not emerge in temporal proximity to their ingestion of the drug. At first blush, this might appear to be a reliable method for determining those individuals whose injuries were more likely due to the drug. That interpretation, however, is based on the false premise that medicine can always find a cause for an injury. In fact, there are many conditions for which medicine frequently cannot find a cause.¹¹⁵ In other words, there is often a measurable background rate of *idiopathic* injuries, i.e., injuries with unknown causes. Plaintiffs' counsel's weeding out process, accordingly, often merely identifies the statistically expected population of patients who coincidentally had adverse events of unknown cause while taking the drug.

At the same time plaintiffs' counsel are reviewing their potential plaintiff population, they will also be looking for an expert witness to provide a specific causation opinion. Generally, plaintiffs' counsel will select an expert who is already prepared to offer a favorable general causation opinion. Plaintiffs' counsel will also select an expert witness who is predisposed toward providing a favorable specific causation opinion. This does not mean that the expert is intentionally biased or insincere in his or her opinion, but it does mean that the expert will enter the process with a preconceived assumption of causality.

By the time the expert and plaintiff are brought together for purposes of a differential diagnosis, the result is effectively preordained. The expert will start the examination from the premise that the substance at issue is dangerous and a likely cause of injury regardless of potential alternative causes. The plaintiff will not present with obvious alternative causes of injury sufficient to shake the expert from the initial presumption. Moreover, in cases where the expert is not the patient's treating physician, the expert will not test the initial diagnosis through ongoing observation and medical treatment.

This "differential diagnosis" bears little resemblance to a differential diagnosis conducted by treating physicians in their regular practice, and cannot provide the type of objective validation that *Daubert* requires for admissibility of an expert specific causation opinion. Trial courts must recognize that there is an inherent "selection bias" at work in mass drug product liability litigation and carefully evaluate the expert's specific causation opinion with this artificial background in mind.

14.2.4 The Parlodel Litigation

Over the past decade, a number of product liability cases involving the prescription drug Parlodel have been working their way through the courts. The Parlodel litigation has resulted in a body of *Daubert* case law that squarely addresses the issues of medical causation expert testimony discussed above and provides a detailed analysis of "all of the components of the 'causation' argument that are available to experts in the most contentious of products liability case[s]."¹¹⁶

There is now an emerging judicial consensus that plaintiffs' experts' causation opinions in the Parlodel litigation do not satisfy the requirements of *Daubert*. Three federal appellate courts, the Eighth, Tenth, and Eleventh Circuits, have unanimously affirmed district court opinions excluding the causation opinions of plaintiffs' experts, and four other published district court opinions

¹¹⁵ See, e.g., Steven A. Kittner, et al, Cerebral infarction in young adults, 50 *Neurology* 890-94 (1998) (despite neurologists' careful review, in 50.5% of cases, no probable cause of stroke in young adults could be identified).

¹¹⁶ Kiely, *supra* note 8. In addition to being used as a case study for legal scholars, the Parlodel litigation was discussed in an article published in the *Journal of the American Medical Association* by an unsuccessful *amicus* for plaintiffs appealing a Parlodel *Daubert* exclusionary ruling to the Eleventh Circuit Court of Appeals in *Rider*. See J. Kassirer and J. Cecil, *supra* note 7.

excluding this testimony were not appealed.¹¹⁷ A few earlier district court opinions, two of which were drafted by the same magistrate judge, have gone the other way.¹¹⁸ The Parlodel opinions thus provide a useful *Daubert* case study of courts that properly evaluated medical causation testimony based on the scientific method and those that do not.

14.2.4.1 Plaintiffs' Allegations Regarding Parlodel

Parlodel (bromocriptine mesylate) is an FDA-approved drug used for a variety of indications, including Parkinson's disease, amenorrhea/galactorrhea (lack of menses), infertility, and acromegaly (a growth disorder). From 1980 to 1994, Parlodel was also approved for the prevention of postpartum lactation ("PPL") in women who elected not to breast-feed. The manufacturer of Parlodel withdrew the drug from the market for this PPL indication following receipt of a number of case reports of strokes, seizures, and myocardial infarctions and an FDA advisory committee determination that there was limited need for pharmaceutical treatment for PPL. The FDA withdrew its approval of Parlodel for the PPL indication in 1995, based on its conclusion that the limited utility of the drug for PPL did not outweigh the possible risks.¹¹⁹

Plaintiffs' experts allege that Parlodel causes vasoconstriction (a narrowing of blood vessels), which they allege can cause stroke, seizures, and myocardial infarction. Plaintiffs' experts concede that the epidemiological studies conducted on the drug have not established a causal link with these injuries and that there is a body of controlled clinical research in humans that has found that Parlodel has the exact opposite effect of causing vasodilation (a widening of blood vessels). Plaintiffs' experts also concede that controlled intact animal research has not shown a causal link between Parlodel and strokes, seizures, or myocardial infarctions in animals. Plaintiffs' experts base their causation opinion on anecdotal case reports (including alleged dechallenge/rechallenge reports), animal research involving limited end points, chemical analogies, a variety of secondary source materials, and differential diagnoses.¹²⁰

14.2.4.2 Opinions Admitting Plaintiffs' Experts' Causation Opinions

The district courts that have admitted plaintiffs' experts' causation opinions have relied primarily on differential diagnoses and the determination that lesser scientific evidence of general causation should be accepted because it allegedly would not be possible to conduct an epidemiological study of sufficient strength to adequately test plaintiffs' experts' causation hypothesis. Thus, one magistrate judge dismissed the lack of any direct scientific evidence supporting plaintiffs' experts' causation opinion, reasoning that "[s]cience, like many other human endeavors, draws conclusions from circumstantial evidence, when other, better forms of evidence [are] not available."¹²¹ In a subsequent opinion, the same magistrate judge sounded a similar theme: "In science, as in life, where there is smoke, fire can be inferred, subject to debate and further testing."¹²² The court was similarly deferential in its review of plaintiffs' experts' specific causation opinions. While noting that there were a number of alternative causes for the injuries at issue, the court found that the "debate creates a question about the weight to be accorded the plaintiffs' experts' opinions, but it does not affect the admissibility."¹²³

¹¹⁷ *Rider*, 295 F.3d 1194; *Hollander*, 289 F.3d 1193; *Glastetter*, 252 F.3d 986; *Dunn*, 275 F. Supp. 2d 672; *Soldo*, 244 F. Supp. 2d 434; *Caraker*, 188 F. Supp. 2d 1026; *Brumbaugh*, 77 F. Supp. 2d 1153; *see also Revels*, 1999 WL 644732 (excluding Parlodel causation opinions on Texas analog of *Daubert*).

¹¹⁸ *Brasher v. Sandoz Pharms. Corp.*, 160 F. Supp. 2d 1291 (N.D. Ala. 2001) (Putnam, M.J.); *Globetti v. Sandoz Pharms. Corp.*, 111 F. Supp. 2d 1174 (N.D. Ala. 2000) (Putnam, M.J.); *Eve v. Sandoz Pharms. Corp.*, 2001 U.S. Dist. LEXIS 4531 (S.D. Ind. Mar. 7, 2001).

¹¹⁹ *See Caraker*, 188 F. Supp. 2d at 1028, 1040.

¹²⁰ *See generally Rider*, 295 F.3d 1194; *Glastetter*, 252 F.3d 986; *Caraker*, 188 F. Supp. 2d 1026.

¹²¹ *Globetti*, 111 F. Supp. 2d at 1180; *see also Eve*, 2001 U.S. Dist. LEXIS 4531, at *75 (quoting *Globetti*).

¹²² *Brasher*, 160 F. Supp. 2d at 1296; *see also id.* at 1297 ("Given the practical unavailability of other forms of scientific evidence, reliance on those that are available is all the more reasonable.").

¹²³ *Id.* at 1299.

Missing in these opinions is any recognition of the requirement in *Daubert* that the experts' causation opinions be based on the scientific method of testing and validating hypotheses. *Daubert* does not permit expert testimony to be admitted based on the smoke of anecdotal reports and inferences, nor does it allow courts to lower the bar of scientific reliability based on a perceived lack of relevant scientific evidence. In accepting plaintiffs' experts' lower showing of evidence, these courts abdicated their gatekeeping responsibility.

14.2.4.3 Opinions Excluding Plaintiffs' Experts' Causation Opinions

By contrast, in the Parlodel cases in which courts have evaluated plaintiffs' experts' opinions based on the scientific method, the experts' testimony has been excluded. These courts have conducted detailed analyses of each of the different categories of evidence discussed above, and their reasoning and conclusions are incorporated in that discussion. The overarching theme in these opinions is the courts' recognition that medical causation opinions are not admissible unless they are based on scientifically tested and validated hypotheses.

As these courts have explained, *Daubert* does not establish a "best efforts" test.¹²⁴ An expert cannot satisfy *Daubert* by arguing that the expert has "used the best methodology available under the circumstance,"¹²⁵ or that the expert has "done the best [the expert] could with the available data and the scientific literature."¹²⁶ Rather, the expert must answer the "key question," whether the "theory being advanced by the expert is testable or has been tested, the methodology of which is what distinguishes science from other fields of human inquiry."¹²⁷ "The hallmark of [*Daubert*'s] reliability prong is the scientific method, i.e., the generation of testable hypotheses that are then subjected to the real world crucible of experimentation, falsification/validation, and replication."¹²⁸ The "testing of hypotheses" is "a critical aspect of the application of the scientific method."¹²⁹ Expert opinions "reposed in the realm of 'may cause' or 'possibly could cause'" must be excluded.¹³⁰ "While hypothesis is essential in the scientific community because it leads to advances in science, speculation in the courtroom cannot aid the fact finder in making a determination of whether liability exists."¹³¹

These Parlodel cases forcefully answer critics of *Daubert* who argue for a lower standard based on deferential review of medical causation testimony:

The *Daubert* trilogy, in shifting the focus to the kind of empirically supported, rationally explained reasoning required in science, has greatly improved the quality of the evidence upon which juries base their verdicts. Although making determinations of reliability may present the court with the difficult task of ruling on matters that are outside its field of expertise, this is less objectionable than dumping a barrage of scientific evidence on a jury, who would likely be less equipped than a judge to make reliability and relevancy determinations.¹³²

The scientific method serves as a bulwark against subjective judgments and inspired guesswork masquerading as scientific knowledge. Courts that ignore the scientific method in their review of medical causation opinions do a disservice to the legal system and disregard the Supreme Court's mandate.

¹³⁰ *Glastetter*, 107 F. Supp. 2d at 1025.

¹³¹ *Dunn*, 275 F. Supp. 2d at 684.

¹³² *Rider*, 295 F.3d at 1197.

14.2.5 Conclusion

Faced with the exacting standards of *Daubert*, plaintiffs' causation experts will often respond with a spaghetti-on-the-wall strategy in the hope that something will stick. The Supreme Court's adoption of the scientific method as the central guide to admissibility provides district courts with the solution they need to untangle the mess. For each strand in plaintiffs' expert's analysis, the questions are the same: Is the expert relying on evidence that has been tested and validated, and does the evidence fit the question at issue? Unless experts can answer both of these questions in the affirmative, they should not be allowed to serve up their opinions to a jury.

As Supreme Court Justice Breyer explained in his concurring opinion in *Joiner*, the evidentiary safeguards imposed by the courts against unreliable science provides an important bulwark against unfounded litigation that can threaten access to needed health care:

[M]odern life, including good health as well as economic well-being, depends upon the use of artificial or manufactured substances.... [I]t may, therefore, prove particularly important to see that judges fulfill their *Daubert* gatekeeping function, so that they help assure that the powerful engine of tort liability, which can generate strong financial incentives to reduce, or to eliminate, production, points toward the right substances and does not destroy the wrong ones.¹³³

While this book has focused primarily on the dangers of *drug abuse*, the potential dangers of *litigation abuse* on the availability of medically indicated pharmaceutical products also poses a threat to patient health that must not be ignored.

¹³³ *Joiner*, 522 U.S. at 148–49 (Breyer, J., concurring).

APPENDIX IA: GLOSSARY OF TERMS IN FORENSIC TOXICOLOGY

Compiled by **H. Chip Walls, B.S.**

Department of Pathology, Forensic Toxicology Laboratory, University of Miami, Miami, Florida

Absolute Method A method in which characterization is based on physically defined (absolute) standards.

Accreditation (1) A formal process by which a laboratory is evaluated, with respect to established criteria, for its competence to perform a specified kind(s) of measurement(s); (2) the decision based upon such a process; (3) formal recognition that a testing laboratory is competent to carry out specific tests or specific types of tests.

Accuracy Closeness of the agreement between the result of a measurement and a true value of the measured quantity.

Acetaldehyde The first product of ethanol metabolism.

Acute Severe, usually crucial, often dangerous in which relatively rapid changes are occurring. An acute exposure runs a comparatively short course.

Acute tolerance The development of tolerance within the course of a single exposure to a drug.

Alcohol dehydrogenase (ADH) The main enzyme that catalyzes the conversion of ethanol to acetaldehyde.

Aldehyde dehydrogenase (ALDH) The enzyme that converts acetaldehyde to acetate.

Aliquot (1) A divisor that does not divide a sample into a number of equal parts without leaving a remainder; (2) a sample resulting from such a divisor.

Analyte The specific component measured in a chemical analysis.

Analytical run (series) A set of measurements carried out successively by one analyst using the same measuring system, at the same location, under the same conditions, and during the same short period of time.

Analytical sensitivity The ability of a method or instrument to discriminate between samples having different concentrations or containing different amounts of the analyte. Slope of the analytical calibration function.

Analytical specificity Ability of a measurement procedure to determine solely the measurable quantity (desired substance) it purports to measure and not others.

Analytical wavelength Any wavelength at which an absorbance measurement is made for the purpose of the determination of a constituent of a sample.

Antemortem Before death, occurring before death.

Ascites An abnormal accumulation of fluid in the peritoneal cavity of the abdomen.

Assignable cause A cause believed to be responsible for an identifiable change in precision or accuracy of a measurement process.

Beer's law The absorbance of a homogeneous sample containing an absorbing substance is directly proportional to the concentration of the absorbing substance.

Bias A systematic error inherent in a method or caused by some artifact or idiosyncrasy of the measurement system. Temperature effects and extraction inefficiencies are examples of errors inherent in the method. Blanks, contamination, mechanical losses, and calibration errors are examples of artifact errors. Bias can be either positive or negative, and several kinds of error can exist concurrently. Therefore, net bias is all that can be evaluated.

Blank (1) The measured value obtained when a specified component of a sample is not present during the measurement. In such a case, the measured value (or signal) for the component is believed to be due to artifacts and should be deducted from a measured value to give a net value due solely to the component contained in the sample. The blank measurement must be made so that the correction process is valid. (2) Biological specimen with no detectable drugs added, routinely analyzed to ensure that no false-positive results are obtained.

Blind sample A control sample submitted for analysis as a routine specimen whose composition is known to the submitter but unknown to the analyst. A blind sample is one way to test the proficiency of a measurement process.

Calibrant Substance used to calibrate, or to establish the analytical response of, a measurement system.

Calibration Comparison of a measurement standard or instrument with another standard or instrument to report or eliminate, by adjustment, any variation or deviation in the accuracy of the item being compared.

Central line The long-term expected value of a variable displayed on a control chart.

Certification A written declaration that a particular product or service complies with stated criteria.

Certified value The value that appears in a certificate as the best estimate of the value for a property of a certified reference material.

Certified reference material (CRM) A reference material one or more of whose property values are certified by a technically valid procedure, accompanied by or traceable to a certificate or other documentation that is issued by a certifying body. [ISO Guide 30: 1981 (E)]

Chain of custody (COC) Handling samples in a way that supports legal testimony to prove that the sample integrity and identification of the sample have not been violated as well as the documentation describing these procedures.

Chance cause A cause for variability of a measurement process that occurs unpredictably, for unknown reasons, and is believed to happen by chance alone.

Check standard (in physical calibration) An artifact measured periodically, the results of which typically are plotted on a control chart to evaluate the measurement process.

Chronic Persistent, prolonged, repeated.

Chronic tolerance The gradual decrease in degree of effect produced at the same blood concentration in the course of repeated exposures to that drug.

Coefficient of variation The standard deviation divided by the value of the parameter measured.

Comparative method A method that is based on the intercomparison of the sample with a chemical standard.

Composite sample A sample composed of two or more components selected to represent a population of interest.

Concentration Amount of a drug in a unit volume of biological fluid, expressed as weight/volume. Urine concentrations are usually expressed either as nanograms per milliliter (ng/ml), micrograms per milliliter (µg/ml), or milligrams per liter (mg/l). (There are 28,000,000 micrograms in an ounce, and 1,000 nanograms in a microgram.)

Confidence interval That range of values, calculated from an estimate of the mean and the standard deviation, which is expected to include the population mean with a stated level of confidence. In the same manner, confidence intervals can also be calculated for standard deviations, lines, slopes, and points.

Confirmation A second test by an alternate chemical method to positively identify a drug or metabolite. Confirmations are carried out on presumptive positives from initial screens.

Control chart A graphical plot of test results with respect to time or sequence of measurement together with limits in which they are expected to lie when the system is in a state of statistical control.

Control limits The limits shown on a control chart beyond which it is highly improbable that a point could lie while the system remains in a state of statistical control.

Control sample A material of known composition that is analyzed concurrently with test samples to evaluate a measurement process. (See also Check standard.)

Correlation coefficient Measures the strength of the relation between two sets of numbers, such as instrument response and standard concentration.

Cross sensitivity A quantitative measure of the response for an undesired constituent or interferent as compared to that for a constituent of interest.

Cross-reacting substances In immunoassays, refers to substances that react with antiserum produced specifically for other substances.

Cutoff level (threshold) Value serving as an administrative breakpoint (or cutoff point) for labeling a screening test result positive or negative.

Cytochrome P450 A detoxifying enzyme found in liver cells.

Detection limit or limit of detection (LOD) The lowest concentration of a drug that can reliably be detected. Smallest result of a measurement by a given measurement procedure that can be accepted with a stated confidence level as being different from the value of the measurable quantity obtained on blank material.

Double blind A sample, known by the submitter but supplied to an analyst in such a way that neither its composition nor its identification as a check sample or standard is known to the analyst.

Duplicate measurement A second measurement made on the same or identical sample of material to assist in the evaluation of measurement variance.

Endogenous Produced or originating within the body by natural processes such as intermediary metabolism.

Enzymes Proteins whose function is to drive the chemical reactions of the body — a catalyst of biochemical reactions.

False negative An erroneous result in an assay that indicates the absence of a drug that is actually present.

False negative rate The proportion of true positive samples that give a negative result.

False positive An erroneous result in an assay that indicates the presence of a drug that is actually not present.

False positive rate The proportion of true negative samples that give a positive test result.

Fume Gas-like emanation containing minute solid particles arising from the heating of a solid body such as lead, in distinctions to a gas or vapor. This physical change is often accompanied by a chemical reaction such as oxidation. Fumes flocculate and sometimes coalesce. Odorous gases and vapors are not fumes.

Hepatocyte Name given to cells within the liver.

Hyperglycemia An excessive amount of glucose in the blood.

Hypoglycemia An abnormally low concentration of glucose in the circulating blood.

Impairment Decreased ability to perform safely a given task.

Infrared Pertaining to the region of the electromagnetic spectrum from approximately 0.78 to 300 microns (780 to 300,000 nanometers).

Insulin A hormone produced in the islets of Langerhans in the pancreas as a response to elevated blood sugar levels. The hormone permits the metabolism and utilization of glucose.

Interferant A chemical compound or substance other than the substance of interest (e.g., ethanol) to which the measuring instrument responds to give a falsely elevated result.

Interfering substances Substances other than the analyte that give a similar analytical response or alter the analytical result.

Interindividual variation Distribution of the values of a type of quantity in individuals of a given set.

Intraindividual variation Distribution of the values of a type of quantity in a given individual.

Limit of quantification (LOQ) The lower limit of concentration or amount of substance that must be present before a method is considered to provide quantitative results. By convention, $LOQ = 10 \times so$, where so = the estimate of the standard deviation at the lowest level of measurement.

Matrix The composition of the biological sample being analyzed, consisting of proteins, lipids and other biomolecules that can affect analyte recovery.

Matrix effects Influence of a component in the analytical sample other than the component being investigated on the measurement being made.

MEOS The microsomal ethanol oxidizing system, an enzyme system in liver that converts ethanol to acetaldehyde.

Metabolite A compound produced from chemical changes of a drug in the body.

Microsomal enzymes Detoxifying enzymes associated with certain membranes (smooth endoplasmic reticulum) within cells.

Ordinal scale Ordered set of measurements consisting of words and/or numbers indicating the magnitude of the possible values that a type of quantity can take.

Outlier A value in a sample of values so far separated from the remainder as to suggest that it may be from a different population.

Perimortem At or near the time of death.

Pharmacodynamics The study of the relationship of drug concentration to drug effects.

Pharmacokinetics The study of the time course of the processes (absorption, distribution, metabolism, and excretion) a drug undergoes in the body.

Physical dependence A state that develops in parallel with chronic tolerance and is revealed by the occurrence of serious disturbances (abstinence syndrome) when drug intake is terminated.

Postmortem After death, occurring after death, of or pertaining to a postmortem examination, an autopsy.

Precision Closeness of agreement between independent results of measurements obtained by a measurement procedure under prescribed conditions (standard deviation).

Presumptive positive Sample that has been flagged as positive by screening but that has not been confirmed by an equally sensitive alternative chemical method.

Proficiency-testing specimen A specimen whose expected results are unknown to anyone in the laboratory, known only by an external agency, and later revealed to the laboratory as an aid to laboratory improvement and/or a condition of licensure.

Psycho Pertaining to the mind and mental processes.

Psychoactive Affecting the mind or mental processes.

Psychochemical A substance affecting the mind or mental processes.

Psychology The science of mental processes and behavior.

Psychomotor Of or pertaining to muscular activity associated with the mental process.

Psychomotor functions Matters of mental and motor function.

Psychosis Severe mental disorder, with or without organic damage, characterized by deterioration of normal intellectual and social functioning and by partial or complete withdrawal from reality.

Psychotomimetic Pertaining to or inducing symptoms of a psychotic state.

Psychotropic Having a mind-altering effect.

Qualitative test Chemical analysis to identify one or more components of a mixture.

Quality assurance (QA) Practices that assure accurate laboratory results.

Quality control (QC) Those techniques used to monitor errors that can cause a deterioration in the quality of laboratory results. Control material most often refers to a specimen, the expected results of which are known to the analyst, that is routinely analyzed to ensure that the expected results are obtained.

Quantitative test Chemical analysis to determine the amounts or concentrations of one or more components of a mixture.

Repeatability Closeness of agreement between the results of successive measurements during a short time (within run standard deviation).

Reproducibility Closeness of agreement between the results of measurements of the same measurable quantity on different occasions, made by different observers, using different calibrations, at different times (between run standard deviation).

Screen A series of initial tests designed to separate samples containing drugs at or above a particular minimum concentration from those below that minimum concentration (positive vs. negative).

Sensitivity The detection limit, expressed as a concentration of the analyte in the specimen.

Specificity Quality of an analytical technique that tends to exclude all substances but the analyte from affecting the result.

Split specimen Laboratory specimen that is divided and submitted to the analyst, unknown to him or her, as two different specimens with different identifications.

Standard Authentic sample of the analyte of known purity, or a solution of the analyte of a known concentration.

Substrate The substance (molecule) acted upon by an enzyme; its conversion to a particular product is catalyzed by a specific enzyme.

Tolerance A state that develops after long-term exposure to a drug. Metabolic tolerance infers a faster removal, oxidation by the liver. Functional tolerance infers a change in sensitivity of the organ to the effects of the drug.

Tolerance interval That range of values within which a specified percentage of individual values of a population, measurements, or sample are expected to lie with a stated level of confidence.

Ultraviolet Pertaining to the region of the electromagnetic spectrum from approximately 10 to 380 nm.

Visible Pertaining to radiant energy in the electromagnetic spectral range visible to the human eye, approximately 380 to 780 nm.

Wavelength A property of radiant energy, such as IR, visible, or UV. The distance measured along the line of propagation, between two points that are in phase on adjacent waves.

APPENDIX IB: COMMON ABBREVIATIONS

Tubocurarine	5	Q					
Valproic acid	3	WAN		[633–635]	[636,637]	[638]	[639]
Venlafaxine	3	B					[640,641]
Verapamil	2	N		[642–644]			[645,646]
Xylene	5	G					[102,647– 650]
Zolpidem	3	B			[651–655]		

KEY: Fraction (extraction): A = acid, B = Base, WAN = weak acid neutral, Ampho = amphoteric, Q = quantanary, O = Other

Pharmacological Classification

1 Analgesics and Antiinflammatory

Nonsteroidal antiinflammatories

Opioids

Central analgesics

2 Cardiovascular/DiureticDrugs

Antiarrhythmics

Antihypertensives

Beta blockers

Calcium channel blockers

Inotropic

Nitrates

3 Central Nervous System Drugs

Anticonvulsants

Antiemetics/ antivertigo

Depressants

Hallucinogens

Psychotherapeutic agents

Antianxiety

Antidepressants

Antipsychotics

Sedatives and hypnotics

General anesthetics

Barbiturates

Nonbarbiturates

Gases

Volatile liquids

Muscle relaxants

Parkinsonism drugs

Stimulants

Analeptics

Amphetamines

Anorexiant

4 Respiratory Drugs

Antihistamines and antiallergics

Bronchodilators

Cough and cold

5 Other

APPENDIX II: SAMPLE CALCULATIONS

Barry K. Logan, Ph.D.

Director, Washington State Toxicology Laboratory, Department of Laboratory Medicine, University of Washington, Seattle, Washington

Alan Wayne Jones, D.Sc.

Department of Forensic Toxicology, University Hospital, Linköping, Sweden

This section presents some typical scenarios based on authentic DUI cases, and the application of some of the issues discussed in Chapter 13. Bear in mind that statutory “per se” alcohol limits are somewhat arbitrary, and that a person’s driving might be influenced below the so-called “legal

limit.” For this reason, the quantitative measurement of blood or breath alcohol, and related calculations, should be one element of any DUI case, and not the entire case.

Example 1. The defendant (male, 175 lb) had been drinking for 3 h, but gulps down a “double vodka,” (assumed to be 2 oz of 40% v/v) immediately before leaving the bar, and is arrested for DUI 15 min later. His BrAC 30 min after arrest is 0.10 g/210 L. Could his BrAC have been below 0.08 at the time of driving?

This question relates to the significance of the last drink as a factor in raising the BrAC. Since this pattern of drinking represents a small bolus on top of a pre-existing BrAC, it is likely that the last drink was substantially absorbed within 15 min, i.e., at the time of the arrest. The small amount of alcohol unabsorbed would not be enough to account for the difference between 0.08 and 0.10 g/210 L. Note that no allowance was made for alcohol metabolism (often called burn-off) in this example. Assuming some alcohol elimination occurred between the time of the arrest and the breath test, this would make it even less likely that the BrAC at the time of the arrest was below 0.08 g/210 L.

It is possible to construct a scenario whereby the defendant’s version could be supported, and might involve some kind of delayed gastric emptying, an unusually low volume of distribution for the alcohol, and a low alcohol elimination rate. This latter scenario, however, is much less likely than the former, and needs to be evaluated in the context of other available information in the case. For example, what was the reason for the driver being stopped in the first place? These situations require the application of some scientific common sense, and the principle of Occam’s razor, namely that the fewer assumptions one has to invoke to explain a set of facts, the more likely that explanation is. Note also that intra-individual variations in absorption and elimination of alcohol make any kind of reconstruction or repeat of the circumstances in question of dubious value.

Example 2. The defendant (male, 230 lb) claims he consumed ten 12-oz beers of 4.2% v/v alcohol content in 1 h, then drove immediately afterward, and was arrested 10 min after his last drink. The BrAC was 0.17 g/210 L, 1 h later. Could the suspect’s BrAC have been below 0.10 g/210 L at the time of driving?

In this scenario, one has to make fewer assumptions in order for the defendant’s BrAC to be below 0.10 g/210 L at the time of driving. Absorption of alcohol after drinking so much beer could result in a delayed peak. The drinking pattern is unusual, however, based on Widmark’s formula it could account for the measured BrAC. Credible corroboration of the defendant’s story would be important in presenting this case to the jury, and would have to be considered in the context of other evidence of his behavior, his driving, his statements at the time of arrest, etc. It has to be said that even if true, this pattern of drinking followed by driving is not likely to engender much sympathy from the jury.

Example 3. The defendant (male, 150 lb) admits to having a few drinks before an accident, but alleges he drank 4 oz of 40% v/v whisky to steady his nerves after the accident. His BAC at the time of blood sampling about 1 h later was 0.15 g/dL. Could his BAC at the time of the accident have been below 0.08 g/dL?

This scenario relates to whether the contribution from post-accident drinking can account for the difference between the measured BAC and an administrative legal limit. According to Widmark’s formula, the contribution to BAC from the post-accident drinking would be approximately 0.08 g/dL. Given the uncertainty in this estimate (~0.06 to 0.09 g/dL), there is a significant possibility that he could have been below 0.08 g/dL at the time of the accident. Important factors to consider would be the accuracy of the estimate of how much post-accident drinking actually took place (if indeed it did), the actual times of the accident and blood sampling, and some corroboration of the pre-accident drinking pattern. A large amount of drinking immediately before the accident could further raise the likelihood of the BAC being below 0.08 at the time of the accident. In some countries, drinking within a certain time period after an accident is itself considered a punishable offense, and certainly displays poor judgment on the part of the defendant.

Example 4. Defendant (male, 230 lb) is arrested and an evidential breath test shows 0.21 g/210 L. He claims he only consumed two 16-oz beers over a 3-h period. Application of Widmark’s

formula shows that the volume of beer required to produce this BrAC is about 230 oz of 3.5% v/v beer. How can this discrepancy be resolved?

The defendant maintains that the discrepancy suggests a malfunction in the breath test instrument. This comes down to an evaluation of the credibility of the defendant's story against the accuracy and reliability of the breath test. Safeguards followed when conducting the breath test, such as duplicate testing, room air blank tests, and simulator control tests with each subject test, will help to validate the accuracy of the result. Again, other factors such as the defendant's driving pattern, performance in field sobriety tests, and behavior at the time of the arrest will either help or hurt his story. It is the experience of most people working in this field that defendants will invariably underestimate their actual consumption, and may not recall the brand of beer or liquor they were drinking.

Example 5. The defendant (female 120 lb) leaves the scene of an accident, but is eventually arrested and a blood sample is collected 4 h later. Her BAC at the time of sampling is 0.05 g/dL. What was her BAC at the time of the accident ?

This is a clear-cut case regarding the validity of retrograde extrapolation, or estimating back. If one assumes that the defendant was fully post-absorptive at the time of the accident, estimating back 4 h and allowing a mean burn-off rate of 0.019 g/dL/h (with a range from 0.009 g/dL/h to 0.030 g/dL/h) would produce a most likely BAC of 0.126 g/dL (range 0.086 to 0.170 g/dL). However, since a BAC plateau might have occurred, especially with food in the stomach, the validity of this assumption of a decreasing blood alcohol curve for 4 h is perhaps open to question.

Another approach, which is more defensible, can be applied if there is a statutory time limit that applies to the measured BAC. For example, there may be a presumption in the law that a BAC within 2 h of driving is representative of the BAC at the time of driving. In this case, estimating back only 2 h, to place the defendant within the 2-h statutory window, is more reliable and produces a most likely BAC of 0.088 g/dL within a range of 0.068 to 0.110 g/dL.

The larger question in this case would be whether the woman was under the influence of alcohol at the time of the accident, and the estimated BAC is only one element of that determination.

Example 6. The defendant has a breath alcohol concentration of 0.16 g/210L. An expert called by the defense claims that the suspect's elevated body temperature (102.9°F) resulting from a fever, raised his breath level over his blood level by 20%. He claims that the defendant held his breath before exhaling into the instrument, raising his BrAC by 10%. He claims that the defendant may have had some acetone on his breath, but not enough to trigger the interference detector on the instrument, resulting in up to 0.009 g/dL apparent ethanol response from acetone. He notes the "margin of error" on the instrument is 0.01 g/210 L. He also claims that alcohol from the defendant's upper airways was picked up by his breath during the expiration, suggesting that the alcohol entering the instrument did not come from alveoli, or deep lung regions of the airway. The net effect is that the defendant's "actual" BrAC could have been as low as 0.08 g/210 L.

This shotgun approach, perhaps tied to one of the other rising BAC scenarios discussed above, is very common in DUI litigation, as it seeks to present a barrage of details attacking the validity of breath testing in general, and this defendant's test in particular. The various assertions need to be evaluated individually. First, if the jurisdiction has separate blood and breath statutes, the blood/breath ratio resulting from elevated temperature is not relevant. Breath holding will elevate breath alcohol concentrations compared with rapid, repeated inspiration and expiration. However, breath holding is not part of the breath test protocol, and a well-documented 15-min observation period can challenge this assertion. The acetone issue is discussed in detail in Chapter 13; however, the amount of acetone required to produce an apparent BrAC of 0.009 g/210 L, would result only from extreme fasting (including abstinence from alcoholic beverages) or diabetes, which is not a transient condition. The defendant's medical records can determine whether he or she is diabetic. The "margin of error" issue is frequently raised when the result is close to the legal limit. What "margin of error" means is not clear; it is certainly not a scientific term. Most instrument protocols that include a control with each breath test will require that the control is within ± 0.01 g/210 L of

a reference value; however, these same instruments will also include optical controls which typically must meet much more stringent parameters. The kinetics of alcohol deposition and evaporation from the airways during inspiration and expiration have been alluded to in Chapter 13; however, the bottom line is that breath testing is recognized as a valid measurement of impairment, and breath alcohol concentration, regardless of the complexity of the respiration physiology, is a valid indicator of intoxication. The best approach in these cases is again to contrast the contrived circumstances that are required for the defendant's version to be valid, with the generally more straightforward explanation that the defendant had consumed too much alcohol, was arrested because of impaired driving, failed field sobriety tests, and gave a breath test that reflects his true breath alcohol concentration and is consistent with his impairment.

Example 7. The defendant has a BrAC of 0.05 g/210 L, and performs field sobriety tests well. To what extent was the subject's driving affected?

One can say with some confidence that certain elements of the driving task are influenced at fairly low BrAC levels even in experienced drinkers. However, certain kinds of driving tasks are more likely to be affected than others. Driving down a straight, country road with no other traffic, in good weather, during daylight hours requires less skill than driving on a busy city street at night, in the rain, with pedestrians around, and distractions in the car such as intoxicated companions or loud music. In a case such as this, one must look at the driver's actual driving performance and determine first if it was impaired, then second if other explanations exist for that impairment besides drinking, including possibly fatigue, drug use, or inattention. This BrAC on its own says relatively little about the extent of driving impairment.

APPENDIX III: PREDICTED NORMAL HEART WEIGHT (G) AS A FUNCTION OF BODY HEIGHT IN 392 WOMEN AND 373 MEN^a

SECOND EDITION

Drug Abuse Handbook

With unparalleled detail and the highest level of authoritative information, the **Drug Abuse Handbook, Second Edition** is the definitive resource for drug-related issues. Dr. Steven B. Karch has produced the preeminent work on abused drugs with contributions from the best minds in the legal, medical, and treatment fields.

Following the tradition of the best-selling original, the second edition presents a comprehensive guide to the pharmacology and pharmacokinetics of abused drugs, and offers an extensive overview of the pathology of drug abuse. It examines criminalistics, pharmacokinetics, neurochemistry, treatment, and drug-related death investigation, and the ethical, legal, and practical issues involved.

More than 40% new material!

- The impact of advances in DNA research on forensic investigations
- The genetics behind sudden cardiac death and other invisible, yet heritable, diseases
- Drug testing methods, protocol, practicality, and applications in the workplace and criminal justice systems
- The neurochemistry of nicotine, methamphetamines, MDMA, and other important drugs of abuse
- The effects of blood doping and the future of genetic performance enhancement
- The implications of the *Daubert* ruling
- Tables of all Scheduled Drugs, Drug Quantitative Analysis Methods, and more
- A glossary of forensic toxicology terms
- Vivid pictures and diagrams illustrating drug pathology and chemistry
